In the light of present knowledge it seemed to me that this was a case in which an Addisonian type of blood picture had resulted from a diet so restricted as to be insufficient in the *intrinsic factor* necessary for interaction with normal gastric juice to produce the substance which stimulates hemopoiesis in pernicious anemia, a case in which the feeding of a diet adequate in animal protein produced a characteristic remission.

I therefore reviewed the case histories of all anemic patients that had been in the University Hospital with particular reference to their dietary

habits. These included 183 cases of pernicious anemia, 164 cases of secondary anemia and 25 cases of chlorosis. Of the chlorotics, 6 gave a history of poor dietary habits preceding the onset of anemia, but none of a degree that could be interpreted as possibly deficient in the sense of case I. In none of the secondary anemia cases was a marked diet deficiency noted. In two cases diagnosed as pernicious anemia the evidence was suggestive.

CASE REPORT

Case II. R. G., a Porto Rican woman of 55, was admitted to the University Hospital on Oct. 15, 1929, with a chief complaint of weakness. After the death of her husband 4 years before, she had become worried and depressed. For the past 3 years she had eaten no meat, practically no vegetables, and had limited her food largely to white bread, milk and coffee. She gradually became weaker and her weight fell from 156 to 136 pounds. She did not have any paresthesias. There were periods of looseness of the bowels. The past history included an attack of filariasis ten years before.

Physical examination showed some pigmentation of the skin. The tongue was smooth and atrophic. Vibratory sense was not tested "because of linguistic difficulties." Reflexes were not mentioned. The spleen was not enlarged. There was some edema of the legs. The urine was not abnormal. The

van den Bergh test gave a negative direct reaction and an indirect reading of 0.65 unit. Fragility of the red cells was within normal limits. A fractional gastric analysis showed a maximum figure of 68 for total acidity and of 34 for free hydrochloric acid.

The blood findings are given in table II.

The blood picture was that of Addisonian anemia, and the feeding of liver extract produced a typical remission. The patient left the hospital on Oct. 31, 1929, and has not been heard from since then. During her stay in the hospital she had no diarrhea but rather a moderate constipation.

Case III. T. B., a white man, aged 75, was admitted to the University Hospital on April 30, 1925, with a chief complaint of weakness and swelling of the legs. Ten years before he had been sent to the penitentiary where he had been until the day of admission. Nine years ago he had begun to have attacks of indigestion with epigastric distress and belching of gas and sour material. He then restricted his diet, avoiding all meat, beans and potatoes. The indigestion attacks became less frequent but did not cease, so he further restricted his food in quantity and quality. In the past year he had become weaker, emaciated and obviously anemic with more recently edema of the legs and increasing constipation. He was finally sent to the hospital because of suspected gastric cancer.

Physical examination showed an emaciated old man weighing 98 pounds. There was a slight yellow tinge of the skin. The superficial arteries were sclerotic. The tongue was not described. The heart was normal.

TABLE II
Blood Findings in Case II

Date	RBC	Hb %	Color Index	WBC	Neut	Lymph	Mon	Eos	Platelets
10/14/29	2,900,000	65	1.12	3,600	31	65	2	2	Some fibrin and prothrombin, slight anemia, no platelets
10/19	Liver extract one vial 11 d								
10/22	4,000,000	84	1.05	3,200					
10/23	3,600,000	81	1.20	4,000					
10/25	3,800,000	85	1.25	5,100	53	41	4	2	WBC's 53, 41, 4, 2. No platelets

and the pulse rate normal The spleen was not palpable and the peripheral reflexes were normal The blood pressure was normal There was moderate edema of feet and legs The urine contained no sugar and no albumin, and the urinary sediment was negative save for occasional hyaline casts A complete gastrointestinal x-ray study was negative Fractional gastric analysis showed a maximum of 98 total acidity and 53 free hydrochloric acid The van den Bergh test gave a negative direct reaction and an indirect reading of "a trace" There was some increased fragility of the red cells, hemolysis beginning at 0.5 and being complete at 0.375 The blood counts are given in table III

in vitamins, especially in vitamins B and C In both of these patients, therefore, it must be admitted that the anemia was due, in part at least, to these factors In case I, however, the diet covered a considerable range of vegetable foods, and many of these in the raw state, so that it seems unlikely that the diet was to any great degree deficient in any vitamins or in hemoglobin-building foods An intelligent and educated person,—he was a Doctor of Philosophy—the patient

TABLE III
Blood Findings in Case III

Date	R B C	Hb %	Color Index	W B C	Neut	Lymph	Mono	Eosin	Remarks
5/1/25	2,880,000	65	1.14	8,250	53	40	6	1	"No reticulocytes"
5/17	2,750,000	50	0.91	4,800					
5/23	2,800,000	65	1.16	7,600	40	50	6	4	

The diagnosis, which the attending physician recorded as pernicious anemia, while made apparently by a process of exclusion, has little to support it in the data at hand No description of the blood smears are found in the record No treatment was given and his condition at the time of discharge was unimproved His subsequent fate could not be learned

The blood findings in cases II and III are graphically shown in chart 2

In the light of case I, meager though the data are, it is suggested that in rare instances an addisonian blood picture may result from a diet so unusually restricted, especially in animal protein, as to be deficient in the *extrinsic factor* necessary for erythropoiesis

Two objections must, however, be considered In the first place, to what extent was the diet of these patients deficient in other respects? Certainly in case II, and probably in case III, the diet was deficient in iron, as well as

well knew the need of diversification in diet, and this he conscientiously sought to achieve within the limits of his convictions Protein lack would appear to be the outstanding, and perhaps the only defect in this patient's diet

Then there is lacking a further important proof namely, that the gastric juice in these cases actually did contain the *intrinsic factor* The presence in all three of these patients of free hydrochloric acid in the stomach contents may be suggestive but is of course no proof of the presence of the *intrinsic factor* Castle, Townsend and Heath³² have observed two cases of pernicious anemia with free hydrochloric acid in the gastric juice, which juice was nevertheless ineffective on incubation with beef muscle. But the fact that in case I the feeding of chicken muscle, milk and egg (foods which do not contain the erythro-

CHART 2

poietic stimulant in a preformed state) produced a typical remission, at least suggests the presence of the *intrinsic factor* in that patient's gastric juice.

The production of an Addisonian blood picture in the manner suggested must be exceedingly rare. So Willson and Evans²⁶ in their series of 111 cases of pernicious anemia noted no significantly abnormal eating habits. A search of the literature has failed to reveal a case quite comparable with that of our first patient. O'Hara and Greval²⁷ reported typical pernicious anemia in a boy of 14 who had lived

largely on bread, milk, potatoes, and candy. Here there may well have been an avitaminosis, as well as iron deficiency. Furthermore the patient had a true achylia. Avitaminosis undoubtedly also played a part in Acknowledged patient, a woman of 30 with edema, and a suggestive blood picture following six months' subsistence on bread, molasses, tea and occasional little salted meat and with history of beriberi 15 years before. The case of Hindu women with pernicious anemia reported by Wills and Edgerton²⁸ is

in animal protein, were also low in vitamins A to C, to which deficiency the authors attribute the anemia. In short, it would seem to occur only in a "super-vegetarian", such as was our patient.

SUMMARY

1 Anemia from dietary causes results only when an unbalanced diet has been persisted in for a long time.

2 The usual result of such an unbalanced diet is a secondary type of anemia, a chloroanemia.

3 The diet fault in these cases is (a) most commonly a lack of iron and hemoglobin-building elements, (b) rarely perhaps a lack of one or more vitamins, or a combination of (a) and (b).

4 The development of pernicious anemia may perhaps be hastened by diet restrictions (probably of certain animal proteins) in those with achylia gastrica (partial or complete lack of intrinsic factor for stimulating erythropoiesis).

5 The combination of avitaminosis, low protein and iron intake may possibly at times produce an Addisonian blood picture (case II, III').

6 In rare instances an Addisonian blood picture may result from a diet inadequate, through prolonged protein starvation, in the extrinsic factor, which is necessary for the formation of the substance for stimulating erythropoiesis (case I).

Anemia Associated With Gastrointestinal Disorders: Clinical Considerations and the Value of Iron in Treatment*†

By CHESTER S. KEEFER, M.D. F.A.C.P. Boston, Mass.

THE relationship between disorders of the gastrointestinal tract and anemia is of considerable importance because it is common, and in some instances the anemia resembles that seen in pernicious anemia. The conditions attracting most attention have been achylia gastrica, sprue, *Dibothriocephalus latus* infestation, multiple intestinal strictures, gastrectomy, hookworm infestation, and the chronic diarrheas. In the past, it has been customary to attribute the anemia to "toxic factors" and most of the cases have been studied from that point of view. In recent years, with the discovery of liver as a potent factor in the treatment of pernicious anemia¹ many of these conditions have been reinvestigated in an attempt to gather more precise information regarding the various factors responsible for the anemia and to evaluate the various therapeutic agents which are most beneficial.

At this time, twenty patients with

anemia associated with chronic dysentery, seven patients with anemia associated with hookworm infestation, and four patients with anemia associated with tuberculosis of the intestine are discussed. No attempt will be made to deal with the question of the relationship between disturbances in gastric function and anemia except to point out that since the recent important work of Castle and his associates² in pernicious anemia, the relationship of faulty gastric function to other forms of anemia is becoming better appreciated. The observation of Strauss³ in the anemias of pregnancy and Mettier and Minot⁴ and Waugh⁵ in chlorotic types of anemia indicate that disorders of gastric function may be of importance in some anemias other than pernicious anemia. However, before final conclusions can be drawn regarding the precise relationship between achylia gastrica and anemias, further observations are necessary.

ANEMIAS ASSOCIATED WITH CHRONIC DYSENTERY

Twenty patients with chronic dysentery and anemia have been studied. The diagnosis of dysentery was made

*Presented at the Baltimore Meeting of the American College of Physicians, March 27, 1931.

†From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard University.

from the clinical picture, culturing the organisms from the stools and finding the characteristic ulcers in the sigmoid on direct examination. All were due to bacillary infection. In the group as a whole all of the features which are characteristic of pernicious anemia were observed. There was atrophy of the papillae of the tongue in nine, gastric anacidity in four, combined system disease in two, retinal hemorrhages in two, and the blood picture of pernicious anemia in five. Other interesting clinical features were the presence of conditions associated with food deficiency in the form of edema disease in six, peripheral neuritis in two, hyperkeratosis follicularis in two, keratomalacia in two and pellagra in one.

Etiology of Anemia In considering the various factors responsible for the anemia, the duration of the diarrhea, the character of the diet, the changes in gastric secretion, the presence or absence of intestinal hemorrhage, and infection were analyzed.

In all of the twenty cases, the diarrhea had been present for two months or longer. It was evident, however, from the study of a number of other patients with chronic dysentery that factors besides the duration of the diarrhea were of importance in producing an anemia because only about twenty per cent of all patients with chronic dysentery develop an anemia. As a result of this observation it was necessary to study the question further in order to determine why anemia was present in some and not in others. As many patients with diarrhea had restricted their food intake and since this increased the nutritional disturbance

the diets of the patients with anemia were investigated with care. It was evident that eighteen of the twenty patients had been on diets which were inadequate both in quantity and quality and it was noteworthy that the two patients who had not definitely restricted their diets had a gastric anacidity. From these observations it was concluded that anemia was more common in the patients with a chronic diarrhea and a restricted diet than in those who had a chronic diarrhea and a normal diet. On the other hand, if in the presence of a continuous diarrhea the diet were not restricted this did not necessarily protect the patient from anemia if gastric anacidity were present. But since gastric anacidity was present in only three of the patients with anemia, it was clear that it was not responsible for the anemia in the group as a whole. In one patient the secretion of acid was only temporarily disturbed, in the other two the anacidity was permanent.

A factor of importance in enhancing the anemia was blood loss. In all of the patients, a few red blood cells were present in the stools. In none of the patients, however, was there a history of a large hemorrhage and none was observed. Furthermore, the anemia improved in spite of continued slight loss of blood when the proper therapy was employed. It appeared, therefore, that blood loss was only a contributory and not the essential factor in producing the anemia.

The relative importance of the enteric infection in the case of bacterial intoxication was difficult to evaluate. As the anemia did not develop in all patients with chronic

entery, and since the anemia improved following various forms of treatment in spite of the persisting dysentery, it is unlikely that infection was of importance as a direct cause but operated indirectly because it caused an ulcerative colitis and diarrhea which interfered with nutrition

From these observations it is concluded that the anemia associated with

stances secreted by the worms, or to infection following the intestinal lesions produced by the worms. There is another factor of importance in any consideration of the etiology of the anemia, namely, malnutrition. In this study, seven patients with hookworm infestation and anemia were observed who recovered from their anemia without the removal of the worms This

CHART I Patient with anemia associated with chronic dysentery recovering following an adequate amount of food

chronic dysentery results from nutritional disturbances which are due to chronic diarrhea and inadequate diets. The part contributed by blood loss, disturbances in gastric function, and infection are not essential. Chart I illustrates the response of the blood in a patient following an adequate diet.

ANEMIA ASSOCIATED WITH
HOOKWORM INFESTATION

The cause of the anemia associated with hookworm infestation remains obscure. In the past, it has been customary to attribute the anemia to chronic blood loss, hemolytic sub-

stances secreted by the worms, or to infection following the intestinal lesions produced by the worms. There is another factor of importance in any consideration of the etiology of the anemia, namely, malnutrition. In this study, seven patients with hookworm infestation and anemia were observed who recovered from their anemia without the removal of the worms. This was accomplished by giving an adequate diet and iron. Liver also was found to be effective in accelerating blood regeneration, but its effect was less conspicuous than iron. All of the seven patients had a light worm burden, although the anemia was marked. This might lead one to believe that in these particular cases, the anemia had a different origin than usually occurs in hookworm infestation. Such an explanation is extremely unlikely and it is well known that although the majority of patients with hookworm infestation and anemia have heavy infestations, there are striking exceptions in which

anemia is present with a few worms, and conversely no anemia may be present with many worms. In view of these observations, factors other than the worm burden must be considered in explaining the anemia that is associated with hookworm infestation. Darling, Barker, and Hacker⁶ called attention to malaria and malnutrition as factors in explaining the severity of some cases and, more recently, Shapiro⁷ has discussed the discrepancy between the degree of anemia and the worm burden in two groups of patients with hookworm infestation, and emphasized the importance of nutritional factors in influencing the development of anemia. From a study of the literature and these seven cases, there appears to be no question but that Shapiro's observations are correct. It is necessary, therefore, to study factors other than the worm burden in any investigation of the anemia of hookworm disease.

The recent observations of Wells⁸ require comment. By direct observation, he has shown that the hookworms attached to the intestine of dogs withdraw blood from the intestine and eject it into the lumen in such a way that it is lost. He suggests that this blood loss is responsible in part at least for the anemia observed in hookworm infestation.

It has been generally recognized that blood loss is of importance in contributing to the anemia in many of these patients and it probably plays a part in many. In the patients whose blood returns to normal following adequate therapy for anemia, in spite of the fact that they continued to carry the worms, there must be other conditions respon-

sible for the anemia. It is likely, therefore, that while chronic blood loss is responsible for a part of the anemia in some of these patients such factors as malnutrition are of greater importance.

Chart 2 illustrates the response of a patient with anemia associated with hookworm infestation recovering following the feeding of liver and iron while he continued to carry the worms.

ANEMIA ASSOCIATED WITH TUBERCULOSIS OF THE INTESTINE

Tuberculosis of the intestine of the ulcerative type is frequently associated with anemia. Observations have been made on four patients with diarrhea resulting from tuberculous enteritis. In all there was an anemia and evidence of malnutrition and deficiency disease. In order to gather more information regarding the influence of nutritional disturbances in producing the anemia apart from the restrictions of the diet, the records of forty-two patients with tuberculosis of the intestines proven at necropsy were studied. The results of this study have been recorded in detail elsewhere⁹. It was found that the patients with ulceration of the intestine with diarrhea, or alternating constipation and diarrhea, were the ones who developed anemia most frequently, whereas if the intestinal function was not definitely disturbed throughout the course of the illness anemia occurred no more often than in fatal cases of pulmonary tuberculosis without intestinal ulceration or in cases of hyperplastic cecal tuberculosis. It appears, therefore, that the presence of diarrhea is an important factor that can lead to

CHART 2 Patient with anemia associated with hookworm infestation recovering from the anemia following the feeding of liver and iron while he continued to carry the worms

*Improvement due to blood transfusion

the development of anemia in these patients Table 1 summarizes the blood findings of the four patients who were studied

Chart 3 illustrates the course of the blood following treatment in a patient with chronic diarrhea due to tuberculosis of the intestines

The occurrence of the various food deficiency disorders in the patients studied is of interest in supporting the thesis that the anemia was largely the result of nutritional disturbances Keratomalacia, beriberi, edema disease, and hyperkeratosis follicularis were attributed to vitamin A deficiency, beriberi to a lack of vitamin B (G),

and edema disease to protein starvation

In the interpretation of clinical features attributed to specific nutritional defects, it is essential to bear in mind that single food deficiencies seldom exist in man In order that single food deficiencies may be studied in animals the diets must be selected with meticulous care When deficiency disorders exist in man, there is no such selection of food for the diet so that it is usually defective in a number of substances This is apparent in any study of nutritional disturbances in man It is not surprising, then, to find multiple nutritional defects in the same indi-

CHART 3 Patient with anemia associated with tuberculosis of the intestines. No improvement following the feeding of liver extract and iron

vidual, and it is such observations that make the precise interpretation of anemia so difficult. As an example of these difficulties, it may be recalled that any or all of the deficiency disorders due to avitaminosis may be present without anemia, so that when anemia is present under these circumstances, its exact cause is difficult to determine with certainty. In spite of this fact, it is well established that anemia does result from a lack of certain substances in the diet and recently Mettier, Minot, and Townsend¹⁰ have shown that vitamin C stimulates blood regeneration in

patients who have anemia associated with scurvy.

The response of the reticulocytes to liver or iron therapy in the cases discussed here has been compared with their response in a series of cases when the anemia undoubtedly resulted from faulty diets. In chart 4 the reticulocyte counts at the peak of the rise have been plotted against the total number of red cells at the beginning of treatment. It is manifest from the chart that the reticulocytes promptly increased following therapy for anemia in all groups and as a rule the lower

CHART 4 The reticulocyte response in the anemias associated with chronic dysentery, hookworm infestation and tuberculosis of the intestine compared with the response observed in patients with anemia due to malnutrition. The circles represent the response in patients with dysentery, the dots, hookworm infestation, the squares, tuberculosis of the intestine, and the triangles, the anemias due to malnutrition.

the red blood cell count, the higher the reticulocytes rose. There were exceptions among the patients with dysentery when the infection was so severe that death ensued, and when recovery followed blood transfusion. If any conclusions can be drawn from the data it would appear that the cases under discussion responded in the same way as those in which the anemia resulted from malnutrition. I feel, therefore that these observations lend support to the idea that the anemia in the patients with dysentery, hookworm infestation and tuberculous enteritis was of the same nature as that occurring in patients with malnutrition.

Observations of Mettler and Minot¹ are of importance in emphasizing the value of optimum doses of iron in anemia resulting from chronic blood loss and restricted diets, and Strauss² has described its effect in the chlorotic anemias of pregnancy with achylia gastrica, and Powers and Murphy¹¹ have reported positive effects in anemias due to chronic blood loss. My associates and I^{12,13,14} have found that iron was of value in the treatment of anemia due to chronic blood loss, restricted diets, anemia of pregnancy, chronic dysentery, hookworm infestation, chronic chlorosis, and some of the anemias of childhood. Furthermore, in some

TABLE 2
Cases of Anemia Treated With Iron

Diagnosis	Number Treated with Iron	No Showing Improvement	No Showing No Improvement
Dysentery	7	6	1
Hookworm	7	7	0
Tuberculosis of Intestines	4	0	4

In studying the response of the anemia to treatment it was plain that no single form of treatment produced a positive effect in all cases. For example, in the anemias associated with dysentery, positive responses were observed following liver extract potent for pernicious anemia, or iron, or various combinations of whole liver and iron.

The effects of iron therapy in some of the cases are instructive. It has been recognized for many years that iron is of value in the treatment of many forms of anemia, but recently an attempt has been made by various observers to define its usefulness with greater precision. The recent ob-

servations of Mettler and Minot¹ are of importance in emphasizing the value of optimum doses of iron in anemia resulting from chronic blood loss and restricted diets, and Strauss² has described its effect in the chlorotic anemias of pregnancy with achylia gastrica, and Powers and Murphy¹¹ have reported positive effects in anemias due to chronic blood loss. My associates and I^{12,13,14} have found that iron was of value in the treatment of anemia due to chronic blood loss, restricted diets, anemia of pregnancy, chronic dysentery, hookworm infestation, chronic chlorosis, and some of the anemias of childhood. Furthermore, in some

cases, we have found that the effect of iron may be enhanced by the addition of whole liver. The results of iron therapy are recorded in table 2. It was given in the form of ferrous carbonate pills ranging between two and five grams a day. The data clearly show that it was effective in the treatment of anemia associated with hookworm infestation, and in some of the anemias due to chronic dysentery. It was ineffective in the patients with tuberculosis of the intestine but in these patients no form of treatment was beneficial due to the severity of the infection.

The results of iron therapy upon the anemia associated with hookworm in-

festation were uniform and in some patients the effect was enhanced by liver. It is noteworthy that this could be accomplished while the patients continued to carry the worms. That iron is a valuable therapeutic agent in the treatment of anemia due to hookworm infestation is common knowledge and the papers of Day and Ferguson¹⁵, Dock and Bass¹⁶, Kobayashi¹⁷, Keefer and Yang¹², Keefer, Huang, and Yang⁹ furnish ample evidence to confirm this statement.

It is clear, then, that iron is a valuable therapeutic agent in the treat-

ment of some of the anemias associated with gastrointestinal disorders, but if it fails, other substances such as liver or liver extract should be administered.

SUMMARY AND CONCLUSIONS

Malnutrition is often an important factor in the production of anemia associated with disorders of the gastrointestinal tract such as chronic dysentery, hookworm infestation, and tuberculosis of the intestine.

Iron and liver therapy can accelerate hemoglobin regeneration in some of the cases.

On the Morbid Anatomy of the Diaphragm*†

By BALDUIN LUCKÉ, *Philadelphia, Pa*

THE diaphragm is probably the most interesting and important of all skeletal muscles. Its general physiological properties are unique¹, it plays a prominent part in a variety of functions of the body. Thus, it is the chief muscle of respiration, and it acts as an important circulatory muscle by propelling venous blood and lymph into the chest cavity. While the physiology of the diaphragm has received much attention, the pathology of this organ has been greatly neglected, with the exception of reports on diaphragmatic hernia and subphrenic abscess, there are but few studies concerning its morbid anatomy. Yet here, as in other organs, a thorough knowledge of morbid structure is a necessary pre-requisite to an understanding of the functional disorders attendant on disease.

It is true that there are relatively few disease processes which affect the diaphragm as primary lesions, but secondary lesions are extraordinarily common. The majority, though not all, of the diseases of the diaphragm are spread from adjacent tissues and

organs in intimate contact with it: the pleurae, the pericardium, the peritoneum, the liver, gall-bladder, stomach, spleen, adrenals, kidneys, pancreas and duodenum.

In the present communication are discussed some of the more common lesions occurring in the diaphragm, namely secondary neoplasm, tuberculous and acute inflammatory reactions, and certain degenerations. In all of these conditions the diaphragmatic muscle suffers impairment or destruction, and hence its function is interfered with to a greater or lesser degree.

NEOPLASMS

Primary tumors of the diaphragm are very rare. There have been reported less than a score of them, all of the connective tissue series: fibromas, chondromas, lipomas and sarcomas. Secondary tumors, on the other hand, are of far more common occurrence than is generally thought. Thus in a series of 164 pathologic diaphragms, I found eighteen secondary tumors. The growths were carcinomas in fourteen and sarcomas in three instances; the remaining tumor was a renal hypernephroma. Of the fourteen carcinomas, five were primary in the stomach, two each in liver, gall-bladder and ovaries, and one each in the lung, esophagus and small intestines. The sarcomas

*Presented at the Baltimore Meeting of the American College of Physicians, March 25, 1931.

†From the Laboratory of Pathology, School of Medicine, University of Pennsylvania, and the Laboratory of Pathology, Philadelphia General Hospital.

were two primary lymphosarcomas of the mediastinum, and one a spindle cell sarcoma of the thigh. In a series of 12 metastatic cancers of the diaphragm reported by Kitain², five were primary in the stomach, three in the breast and one each in the uterus, gall-bladder, bronchi and tongue. Thus in both Kitain's and the present group of tumors the primary tumor was conspicuously most often located in the stomach.

In some of the cancers arising from the stomach, liver and gall-bladder it was difficult to decide whether the tu-

mors had spread to the diaphragm by direct extension or by metastasis. In the other tumors metastatic distribution was certain.

The gross appearance of the diaphragm varied considerably. In the cancers there was generally a diffuse flat-nodular infiltration beneath one or both serous surfaces (figure 1). Since the majority of these tumors had their primary seat in abdominal organs abutting on the diaphragm the peritoneal surface was generally more heavily infiltrated than the pleural surface. Microscopic examination showed the

FIG. 1. Secondary adenocarcinoma of diaphragm. From a white man, aged 70 years. The primary tumor was an ulcerating cancer of the pylorus. There were metastases to the liver, both lungs, the retrosternal lymph nodes and the capsule of the spleen. The photograph shows the abdominal surface of the diaphragm invaded by flattened tumors.

masses occupying the subserous lymph-channels. From these they ramified, again largely by way of lymphatics, throughout the diaphragmatic muscle (figure 2) grossly appearing as irregularly distributed whitish bands or nodules. While the lymphatics appear to play the chief rôle in the dissemination of carcinoma through the diaphragm, as suggested many years ago by Rajewsky³, two tumors in the present series were probably distributed by way of the blood-stream, namely, the hypernephroma and the spindle cell sarcoma.

Not all of the neoplasms had the gross appearance described above, two of the sarcomas occurred as isolated large roundish masses each the size of a lemon.

The degree of destruction of the diaphragm was generally considerable. The appearance shown in figure 2 is typical of the majority of the cases. It is seen that large areas of the muscle are completely replaced by tumor cells.

TUBERCULOSIS

Tuberculous involvement of the diaphragm is nearly always secondary to some tuberculous focus in adjacent tissues. In the present series the diaphragm showed tuberculous lesions in 35 cases out of a total of 164 diaphragms examined. Curiously, the peritoneal surface was more often affected than the pleural surface, even when the primary focus was in the lung or the pleura. Thus in the case illustrated by figure 3 the abdominal side of the diaphragm was plastered with caseous flat masses, while the pleural surface was smooth and glossy. The primary focus in this case was a tuberculous bronchopneumonia. The gross appearance of the tuberculous lesions was the same as in tuberculosis of serous surfaces in general; there were found isolated miliary and conglomerate tubercles, or more often a true tuberculous serositis. In the later case one or the other surface of the diaphragm was coated with a thick

FIG 2 Metastatic carcinoma of diaphragm, primary in bile-ducts. From a white man, 53 years old. There were metastases to the lungs, mediastinal, retroperitoneal and mesenteric lymphnodes. The photograph (low power) shows the tumor masses largely confined in greatly distended lymphatics. There is extensive replacement of diaphragmatic muscle.

yellow caseous exudate in which no discrete tubercles were found (figure 4) In either form, adhesions to the lung, the liver, stomach or other adjacent organs were commonly observed

In a considerable number of cases the tuberculous lesions were not confined to the serous surfaces, but tubercles were actually present within the diaphragmatic muscle, not infrequently causing much destruction It is very probable that the frequency of muscular involvement is due to the rich

lymphatic supply through which the infection is distributed Indeed of all muscles, the diaphragm probably is most often the site of tuberculous lesions, for tuberculosis of the skeletal muscles is of rare occurrence¹

ACUTE INFLAMMATORY REACTIONS AND THEIR CONSEQUENCES

The occurrence of "diaphragmatic pleurisy" and of "diaphragmatic peritonitis" has long been recognized Inflammation of the muscle of the diaphragm however has received very

FIG 3 Tuberculosis of diaphragm The peritoneal surface is studded with nodules and conglomerate tubercles between which an exudative reaction may be seen In a negro, aged 26 years, with primary tuberculosis bronchopneumonia Histologic examination showed extensive invasion of the muscle

little attention, although Rohrer⁵, and later Coplin⁶, described in detail the muscular changes generally complicating inflammation of the serous covering. In the present series there were 25 instances of diaphragmitis. Not only was there an inflammation of one

quently a delicate fibrin net could be seen between the muscle fibres. The capillaries were engorged, and the lymph channels prominently distended.

In our series the primary lesion was pneumonia in fifteen cases, peritonitis due to infection of some abdominal

FIG 4 Tuberculosis of both surfaces of diaphragm. From a negro, 26 years old. The pleural surface is covered with a thick layer of caseous material which merges with a caseous tuberculous (visceral) pleurisy. The photograph shows several large caseous areas within the muscle near the pleural surface. The primary lesion was a typical chronic pulmonary tuberculosis, with terminal miliary tuberculosis.

or both serous surfaces, but in every instance the muscle showed definite changes. In some, these consisted chiefly of degenerative lesions, to be discussed in the next section. In the majority there was present in addition a true myositis. The degenerated muscle fibres were separated by an edematous fluid containing polymorphonuclear leucocytes and occasional mononuclear histocytes. Not infre-

quently a delicate fibrin net could be seen between the muscle fibres. The capillaries were engorged, and the lymph channels prominently distended. In our series the primary lesion was pneumonia in fifteen cases, peritonitis due to infection of some abdominal

viscus in eight instances, there was one case of general sepsis due to erysipelas and one case of endocarditis. In the latter two cases the infecting agent was probably conveyed to the diaphragm by the blood-stream. The inflammatory lesions of the diaphragm are probably of very great clinical importance. Rohrer⁵ believed that such lesions occur in every case of pneumonia, an opinion that I am not

inclined to share. I have found many cases of pneumonia without lesions of inflammatory, as contrasted with purely degenerative, character in the diaphragm. Undoubtedly, however, diaphragmitis is of much greater frequency as a complication of pneumonia than is generally recognized. The degeneration of the muscle cells and their separation by inflammatory edema and exudate probably interfere greatly with the efficiency of muscular contraction.

But not only are the acute lesions of significance, but their consequences are likewise of importance. Organization of exudate covering the serous surfaces leads to adhesions, and the repair of the inflammatory foci in the muscle to patches of fibrosis (figure 5).

DEGENERATIONS AND INFILTRATIONS

It has just been stated that various degenerative changes occur in diaphragmatic inflammation. The most common of them are vacuolar degeneration, cloudy swelling, Zenker's hyaline degeneration and fatty degeneration. Of these vacuolar (hydropic) degeneration was most often seen in the cases of diaphragmitis. Here and there muscle cells were swollen and without structural details, there were smaller or larger irregularly shaped vacuoles within the cells. These vacuoles usually contained a faintly eosin-staining fluid (figure 6). Other muscle cells showed cloudy swelling. This was most readily recognized in fresh unfixed and unstained frozen sections.

FIG. 5. Subacute diaphragmitis. From a white woman, aged 40 years, who died from widespread lobular pneumonia and staphylococcal abscesses of the lungs. There are scattered small areas of partly organized exudate as well as some older scars. An invasion of fatty-areolar tissue is present.

or teased preparations. The affected cells were large, their striations hazy or entirely lost, the cytoplasm lumpy or granular.

Of the various degenerations of the diaphragm Zenker's hyaline necrosis has received most attention. The subject has been reviewed so recently and so thoroughly by Wells⁷ that no further discussion is here necessary. Wells emphasizes the great frequency with which the diaphragm exhibits this form of degeneration in pneumonia and indicates the probability that such muscular degeneration may be an important factor in determining respiratory failure in this disease.

Besides these acute degenerations, certain changes of more chronic na-

ture are found not infrequently in the diaphragm. These are the so-called fatty degeneration and fatty infiltration. The former is characterized by the appearance of visible fat droplets within the muscle cells, and by many writers is regarded as an indication of irreversible degeneration. (Figure 7)

In the present series such fatty degeneration was found most often in cases of severe anemia and in chronic circulatory disturbances, i. e., under the same conditions that fatty degeneration affects the cardiac muscle. Indeed the fatty changes of the diaphragm are very similar to those of the heart; they are patchy in distribution, occurring grossly as yellowish flecks on the cut surface of the reddish-gray diaphrag-

FIG 6 Vacuolar (hydropic) degeneration of diaphragm. From a white man, aged 52 years, who died from extensive lobular pneumonia. The diaphragmatic pleura is covered with a fibrino-cellular exudate. The muscle cells are swollen, vacuolated, and many have a lumpy or hyaline cytoplasm. The intermuscular tissue is edematous.

matic muscle Microscopically, the distribution of the affected fibres is extremely irregular, one usually finds markedly degenerated muscle cells bordered by structurally normal fibres Some fibres contain but traces of visible fat, in others the entire cell is packed with droplets which obscure all details

Fatty degeneration of the diaphragmatic muscle has been studied by a number of observers^{8,9,10,11}, there is general agreement that of all skeletal muscles the most active, the diaphragm, shows this lesion most often

Fatty infiltration is a very different process Under normal conditions the

subserous tissues of the diaphragm contain small amounts of fat, but never in as great a quantity as normally occurs in the subserous areolar tissue of the heart Under certain conditions there may accumulate a considerable layer of fat, which, when the muscle fibres are atrophic, penetrates between them, thus interrupting their continuity

DISCUSSION

It is very difficult to evaluate the significance of the lesions described Certainly it is true that the efficiency of the diaphragm depends above all on the ability of its component muscle fibres to contract properly In tu-

FIG 7 Fatty degeneration of diaphragm (Sudan III stain of frozen section) From a white woman, 62 years old, who had suffered from myocardial disease for several years She died from decompensation and there was marked dilatation of the heart, the myocardium had a striking mottled yellow to yellow-brown appearance, the tigered mottling was best seen beneath the endocardium of the papillary muscles Microscopically there were numerous typically fatty degenerated muscle fibres in the diaphragm usually lying alongside of structurally normal fibres

mors, in tuberculosis, in diaphragmitis and in degenerations it may be assumed that the functional powers of the muscle as a whole are considerably impaired, for all of these disease processes are attended by loss of contractile substance. Such impairment of diaphragmatic function may have serious consequences when the respiratory or circulatory mechanism is at fault.* Unfortunately it is very difficult to determine after the death of the patient from clinical records what ef-

fect any diaphragmatic lesion discovered post mortem had on the course of the disease. The true significance of diaphragmatic lesions is yet to be worked out, and this can be done only through experiment and through collaboration of clinician and pathologist in a large series of cases.

*For a discussion of the pathological physiology of the diaphragm reference should be made to the monographs of Eppinger¹² and of Hitzenberger¹³, as well as to the writings of Landis¹⁴.

The Heart and the Diaphragm*†

By I M TRACE, M D , F A C P , *Chicago, Ill*

WALSHE, writing in 1871 about the clinical importance of the diaphragm, said "I am persuaded much of their silence depends less on immunity from disease of this musculo-fibrous septum, than upon the rarity with which it is examined post-mortem. Clinical ignorance is the necessary result of this neglect." And even at present the diaphragm hardly gets the clinical considerations its location and functions warrant.

A musculo-fibrous structure, lined with pleuro-pericardial serosa on its upper and peritoneum on its lower surface, it separates the thoracic and abdominal cavities and is in close contact with the cardio-respiratory organs and important abdominal viscera.

Symptomatically sharing the troubles of its neighbors on the north or the comrades on the south, it may be visited by such remote calamities as miliary tuberculosis, trichiniasis, pernicious anemia and scurvy. It is said to undergo degeneration in severe congestive heart failure and marked emphysema (Zahn, Falkenstein, Hitzemberger¹).

The phrenic is its chief motor nerve and its muscle tone is nicely balanced

by an interplay of the sympathetic and parasympathetic forces.

Next to the heart it is the most important muscle in the body (Falkenstein). Structurally and functionally it bears a rough analogy to the heart muscle. It is striated, its contractions are rhythmic, tetanic in character, of long duration, with short intervals of rest. It works unremittingly from the cradle to the grave, but its action is both voluntary and involuntary. Considered at one time the main muscle of respiration, its importance was somewhat dimmed by the surgeon. Unilateral paralysis was found to be no great handicap and even bilateral phrenicotomies were survived. The diaphragm is one of the important muscles of respiration and its chief business is to keep the lower lobes inflated and properly aerated.

The circulatory function of the diaphragm is often lost sight of. The upright posture of man makes the backflow of venous blood difficult. During an inspiratory diaphragmatic contraction the intra-abdominal pressure increases, the intrathoracic becomes negative and the diaphragm acts as a suction pump upon the returning venous blood. The liver, the great reservoir of venous blood, is compressed by the diaphragm, "like a wet mushroom by a grasping hand."

*Read before the Chicago Medical Society, March 18th, 1931.

†Received for publication, April 20, 1931.

(Wenckebach), and its blood is forced out into the great veins of the thorax. With each diaphragmatic contraction the intra-abdominal cavity is enlarged and the intracardiac pressure is diminished, with the heart moving caudally, thus facilitating the better filling of the heart chambers.

The pressure within the abdomen varies with inspiration, body positions and distention of the hollow viscera. The intrapulmonary pressure is subject to marked and at times sudden variations. There is a reciprocal and antagonistic relationship between the heart and the diaphragm, and thus between the two cavities, by the diaphragmatic abdominal reflex of Sherrington. A positive hypertonic reflex of the diaphragm is often associated defensively with a negative hypotonic cardiac reflex (dilatation) and a positive hypertonic cardiac reflex is helped by a negative hypotonic diaphragmatic reflex. The diaphragm thus acts as a buffer, protecting the thoracic viscera from excessive intra-abdominal pressure and the abdominal contents from sudden variations in intrapulmonary pressure.

To function efficiently the diaphragm must be unhampered in its movements and maintain an optimum position in the thorax. Its central tendon is at the eighth dorsal spine and it reaches the fourth interspace on the right, the fifth rib on the left anteriorly; posteriorly, the eighth rib on the right and the eighth interspace on the left. Its position is the result of the normal pulmonary pull, muscle tone, and the width of the lower thorax. It varies with the pressure in the thoracic and abdominal cavities and is marked-

ly influenced by posture⁴, being lowest when the person is standing and highest when he is supine; sitting produces no appreciable change in the normal diaphragm.

Even from this fragmentary anatomico-physiologic survey it is quite evident that the diaphragm is a friendly intermediary and helpful ally, and it is hardly surprising to find it parading at times in the clinical garb of its neighbors, especially the heart.

Young adults and children not infrequently have pain in the lower axillary regions on walking or running. When the pain is on the left side the heart comes under suspicion. If the heart is found normal, as it usually is, the pain is due to spasm of the diaphragm.

A fit of laughter is likely to provoke similar discomfort as the following case will illustrate.

A Gypsy of forty-five, complained of pain in the precordium, radiating to the shoulder, of three days' duration. The pain was severe and was aggravated by exertion, by loud and fast talking. The cardio-circulatory apparatus was normal. Further questioning brought out that while in a speak-easy, swapping stories with his comrades, an especially good one caused a fit of laughter and the pain appeared shortly after. The fluoroscope showed jerky movements of the left diaphragm. Strapping relieved the pain immediately.

In effusive pericarditis the diaphragm may become inflamed by contiguity. Nausea, vomiting and hiccoughing may dominate the picture and obscure the diagnosis. When with the diaphragmitis there is also a phrenic involvement, pain in the shoulder and dysphagia may be so severe that the mere sight of water or

food will cause pain, the so-called hydrophobic type of an effusive pericarditis⁶ Swelling and tenderness of the liver may come on before fluid can be demonstrated in the pericardial sac clinically and be quite puzzling It is due to an embarrassment of the vena cava inferior by the faulty movements of the right diaphragm

The sequence of events may be reversed A left sided diaphragmatic lesion may cause severe heart pain

A man of twenty-four was awakened at two in the morning with severe anginal pain radiating to the shoulder, which required morphia The pain recurred two or three times daily for about three weeks, the patient running a septic temperature The chest showed nothing abnormal Fluoroscopy was likewise negative, the left diaphragmatic outline being clear, regular in outline and its lateral half moving freely with some haziness in the left costo-phrenic angle The needle obtained 5 cc of slightly cloudy fluid Three weeks after the onset, edema appeared in the epigastrium, slight bulging soon following Incision revealed pus in the left subdiaphragmatic space close to its central portion With drainage the fever subsided, the pain disappeared and the recovery was speedy The cause of the abscess remained obscure

When a chronic pericarditis works through the diaphragm and involves the capsule of the liver, Pick's pseudocirrhosis is likely to result Its classical diaphragmatic phenomena of epigastric systolic retraction during inspiration and Broadbent's systolic tug posteriorly are familiar to every clinician It is not generally known that occasionally an unaccountable right pleural effusion⁷ may be its earliest manifestation, more so when associated with an enlarged liver The compromised right diaphragm apparently interferes with the action of the

right heart or compresses the supra-diaphragmatic portion of the vena cava inferior (Hanot⁸)

Milder forms of an adherent pericardium often entirely escape clinical detection Demonstrating the immobility of the apex by percussion, while often diagnostically helpful, is not always possible in women, in the obese and in the emphysematous The fluoroscope with the patient in the left lateral position will diagnose⁷ the condition with certainty and ease Normally the heart moves away from the dependent left chest on deep inspiration, this movement is most marked in the lower left cardiac contour With an adherent pericardium this movement is slight or entirely absent With the patient in the erect position there may be present an upward systolic tug⁹ of the left diaphragm

Dyspnea may at times be the outstanding symptom of a chronic diaphragmitis It is a good clinical rule to suspect the diaphragm, when the dyspnea is out of all proportion to the findings in the chest

Not infrequently following an effusive pleurisy of some duration, dyspnea appears upon exertion Re-examination shows marked dulness with diminished breath sounds, ectasia is absent, even retraction of the intercostal spaces may be present Fluid is still suspected, but the tap is dry The fluoroscope shows no fluid, but haziness and immobility of the diaphragm Needling, as suggested by the Japanese, stimulates the lazy diaphragm to increase its respiratory excursions and to keep the lungs inflated Pryor describes severe dyspnea in pneumoconiosis involving the diaphragm The

patient is pale, the heart is small and tube-like; the apex beat is feeble and the heart tone distant. When fibroid phthisis invades the diaphragm, dyspnea may become quite troublesome.

Sudden and severe dyspnea is likely to come on following operations on the upper abdomen or injury to the chest wall. The clinician suspects an acute pulmonary atelectasis; the physical findings may, and the x-ray does diagnose the condition. While it is conceded that bronchial obstruction by viscid secretion is the main factor⁹ in the pathogenesis of a massive pulmonary collapse, the defensive splinting of the thoracic wall and of the diaphragm, already handicapped by the supine posture, play no small contributory part by abolishing or diminishing the diaphragmatic excursion and interfering with the efficient respiratory dilatation of the lungs and their ability to expel the bronchial secretion¹⁰. Yandell Henderson¹¹ suggested that carbon dioxide be given at the end of the anesthesia to induce deep respirations and properly inflate the lungs.

Eventration or relaxation of the diaphragm, whether congenital or acquired, is usually left sided. The raised left diaphragm does not compress the pulmonary base but lifts and moves the heart to the right. Most often symptomless, it will occasionally give rise to a cardio-diaphragmatic syndrome of precordial distress, dyspnea and angina-like pain upon a full stomach or intestinal distention in the gonadal and adipose dystrophies and in the myocardiopathies³.

The findings of basal tympany with diminished breath sounds, the apex in the fourth interspace, with the trachea

displaced to the right, while suggestive, are nearly always overlooked and the diagnosis is made by the fluoroscope. The left diaphragm is high, its outline is regular but faint, it may show paradoxical movements and easily moves upward when pressure is exerted upon the abdomen.

Any one past forty with a girth of generous proportions is well acquainted with the discomfort in the chest, fullness of the head and the turgescient face when, on a full stomach, he is called upon to lace a shoe. The increased abdominal pressure moves the diaphragm up and temporarily embarrasses the circulation. Flatulence frequently provokes extrasystoles, and that angina pectoris is more prone to appear upon a full stomach is a well known clinical fact. One wonders if the frequency of acute coronary thrombosis, masked as an acute indigestion, at the height of a generous banquet, is not due to embarrassed filling of already sclerosed coronaries by a distended stomach pressing up the diaphragm against a diseased heart.

Indeed, any factor favoring an increased intra-abdominal pressure is likely to call forth circulatory difficulties, especially in the obese, in those of sthenic habitus, and in the gravidæ. Dietlen⁴ maintains that in the obese with dyspnea the poor or absent mobility of the diaphragm brings about deficient pulmonary ventilation and venous disturbances in the thoracic and abdominal cavities.

It is not uncommon to see men of sthenic habitus in the fourth or fifth decade, short of neck, broad of chest, red of face, with tense muscular abdominal walls, complain of some short-

ness of breath and precordial distress upon exertion. The thickened arteries, the aortic configuration of the heart with the apex displaced to the left, and short systolic murmurs heard best or appearing only during expiration, logically enough point to the heart, but the fluoroscope shows a high diaphragm and a squatty left heart silhouette well buried in the diaphragmatic shadow. The electrocardiogram shows left axis deviation. In the obese the third lead may show complete inversion¹².

It is hard to ascertain in these cases just what part the heart plays in the production of the symptoms. It is difficult to absolve it from all guilt, since Pearce³ has shown experimentally that the abdomino-visceral reflex responsible for the clinical syndrome of dyspnea and cardiac distress does not affect the normal heart, but only when the myocardium is injured.

About the seventh month of pregnancy the enlarging uterus widens the lower thorax¹³, flattens and pushes up the diaphragm. The apex is raised and rotated to the left, basal râles and even murmurs may appear (Dietlen¹).

A para two of twenty-six, eight months pregnant, complained of dyspnea upon exertion and edema of the ankles. There was no history of rheumatic infections or previous cardiac discomfort. The heart was apparently out to the left with a short systolic mitral murmur not transmitted. Left axis deviation was present in the electrocardiogram. It was interpreted as a normal heart temporarily mechanically embarrassed by the increased intra-abdominal pressure. Six weeks after delivery the heart and the electrocardiogram were normal and the patient in the best of health.

Another gravida of thirty with a very large abdomen had dyspnea and annoying extrasystoles. Delivery relieved her of both.

Mackenzie¹³ explains the cardiac discomfort in the gravidae by the embarrassment of the right heart by the lessened respiratory movements. The latter obviously are hampered by the high and flattened diaphragm. Normal hearts withstand this temporary load quite well. In diseased hearts with the right ventricle already considerably overtaxed as in mitral stenosis, the increased load may lead to serious cardiac failure or acute suffocative pulmonary edema.

The following case is very instructive.

A para three, with a mitral stenosis, when eight months pregnant developed some cough and dyspnea upon exertion. When almost at term, during an obstetric examination and while flat on her back, she became cyanotic, coughed incessantly, and an alarming pulmonary edema quickly supervened. Only heroic treatment saved the patient. Rest in bed with digitalis carried her to term, when she was delivered by Dr. Louis Rudolph quite uneventfully in a semi-sitting position.

The abnormally high diaphragm is not the only source of diaphragmatic dysfunction¹. The low diaphragm when pronounced, is productive of a goodly share of chronic invalidism. Its owner is nearly always thin and pale, with a long and narrow chest and a protuberant ptotic abdomen. The extremities are cold and the blood and pulse pressure are low. The abdominal organs are palpable. Nearly always the victims of numerous poorly defined digestive complaints, they are not infrequently subjected to many unnecessary and repeated abdominal operations. Frequently circulatory disturbances assert themselves, dizziness, dyspnea, palpitation, and fatigue upon exertion bring them to the physician. These

patients present all the symptoms of an effort syndrome the heart is small, the pulse weak and the muscles flabby. The fluoroscopic examination shows a narrow heart hanging suspended like a drop from the large blood vessels. The diaphragm is low, with poor respiratory mobility, and is definitely separated from the cardiac shadow. The poor filling of the cardiac chambers causes a relative arterial anemia with the subjective sense of exhaustion and the suspended heart, lacking its diaphragmatic support, is likely to produce such bizarre findings as a paradoxical pulse or even a tracheal tug. (Wenckebach¹) A well applied abdominal support quickly brings relief. Prolonged rest in bed,

hyperalimentation, aided by insulin, as suggested by Falta, often improve the general condition remarkably.

The physician, who in physical diagnosis of the lungs takes into consideration the depth and shape of the thorax, the thickness of the parietes, the position of the heart and the mobility of the diaphragm, may profitably be on the alert in evaluating cardiac symptoms also, in connection with two important factors the position and the mobility of the diaphragm. He will be rewarded by a better understanding of the mechanism of some symptoms and by fewer diagnostic errors, and the patient will profit by more intelligently applied therapeutic procedures.

Malignancy in the Lung: Including Eight Primary Carcinomas With Autopsy Findings*†

By HENRY MONROE MOSERS, A M , M D , F A C P , *Brooklyn, N Y*

ROBERT J Graves, of Dublin, who so clearly described exophthalmic goiter that the condition is still called Graves' Disease, in a clinical lecture¹ on the Practice of Medicine, delivered nearly ninety years ago, wrote "I shall conclude this lecture with the description of a singular and uncommon disease of the lungs. Rare diseases should not be looked upon as mere matters of curiosity, but should be attentively studied with the view of enabling us to recognize the true nature of similar cases when they again occur." He continues, "The diagnosis of encephaloid tumors of the lungs was, a few years ago, completely impossible, but, I trust, that ere long we may be enabled to arrive at some degree of certainty, even in this difficult and obscure branch of thoracic pathology."

Morgagni², (1682-1772) who laid the foundation of pathological anatomy, was probably the first to publish the results of several autopsies on lungs that might be diagnosed as cancerous, and were so interpreted by him

*From the Medical Service, Kings County Hospital, Brooklyn, N Y

†Read at a Meeting of the Brooklyn Society of Internal Medicine, November 28, 1930

It is probable that the first of the cases which he published as cancer of the lungs was really an example of primary lung tumor. In this case, he describes the disease of a man sixty years old, which was accompanied by cough and copious expectoration of a yellowish, rather crude material, rarely but then distinctly stained by streaks of blood. At autopsy, the lung was found extremely hard with adhesions to the pleura and mediastina, and nothing else but an "ulcus cancrosum in the right lung"³

Adler³, in his masterful study of Primary Malignant Growths in the Lungs and Bronchi, states that "lung tumors were absolutely unknown in ancient and medieval medicine until the time of Morgagni." This statement is no doubt true from all our known medical literature concerning medical conditions of ancient and medieval times. It seems impossible to the writer that metastatic growths from malignancies in other organs never occurred or were never found in the lungs of those afflicted. It is hoped that at some later date accounts of such new growths in the lungs will be found in the writings of physicians of the ancient times. The belief that

primary neoplasms of the lungs are among the rarest forms of disease has persisted for centuries, and it is only within the last few years that this belief is becoming changed, because of the comparatively great number of tumors of the lung being found and studied. For several years there has been a growing belief that intra-thoracic cancers are increasing in frequency. This belief is being confirmed more and more by recent reliable statistics. In a study of the incidence of primary carcinoma in the lung, Rosahn¹ concludes that "the post-mortem incidence of primary carcinoma in the lung is steadily increasing, and this increase is real and absolute." Whatever may be the explanation, primary carcinoma in the lung is more common now than formerly. The cause of this greater frequency of occurrence is not known. This increase was commented upon by Adler² who published his study in 1912, and who did not suggest any reason for it. Davidson³, of London in a study of

cancer in the lung, published in 1930, states that "it seems reasonable to suppose that for an explanation of the increase of primary carcinoma in the respiratory tract, we must look to some factor which, since the period of the War has begun to operate in greater degree, and which, through the production of specific tissue irritation, may account for this hitherto unusual localization of malignant disease in such individuals as are especially susceptible."

In a large, general hospital such as the Kings County Hospital, with an average daily census of 1710 patients, ample opportunities are presented for the study of malignant conditions in the lungs, whether primary or secondary. It has been the privilege of the writer to review the appearance of malignant diseases at the Kings County Hospital during the decade from 1920 to 1930, and in addition to include eleven months of 1930. The following figures are presented of malignant tumors, Kings County Hospital

TABLE I

Patients with malignant tumors in the lungs may be divided into three general classes for diagnosis

First, those upon whom a diagnosis can be made only on post-mortem examination, because of the absence of any general or pulmonary symptoms, except weakness and emaciation, or because the patient is seen only when moribund, and the usual physical findings of malignant tumor in the lungs are masked by other conditions

Second, those upon whom a diagnosis can be made easily by reason of evidence of tumor growth in other parts of the body, in addition to the pulmonary findings

Third, those upon whom a diagnosis of new growth in the lungs can be made because of the history, the course of the disease, the physical findings and the absence of tumor growth in other organs

The presence of a malignant tumor in the lung is not always an easy matter of diagnosis, and unless the growth causes enough discomfort for the patient to seek a physician, the condition may not be discovered during life

CASE REPORTS

Case I On November 22, 1927, M. J., a woman 82 years old, was admitted to the County Hospital with a cellulitis of the scalp. Ten days before admission she

tient had fallen down stairs and had received a scalp wound which became infected. The cellulitis was properly cared for, but the patient's general condition was poor, apparently due to her eighty-two years of age. Three days before her death, or seventeen days after her admission to the hospital, the patient was drowsy, became comatose and died. The belief was that she had a generalized atherosclerosis and died from kidney failure. However, we were fortunate enough to have permission for a post-mortem examination. The histological findings of interest to us at the present time are as follows. The lungs showed emphysema, chronic fibroid pneumonia, congestion and edema and an area of epidermoid carcinoma. The liver showed chronic passive congestion. The kidneys showed a chronic glomerulonephritis. Here we have a primary carcinoma of the lung, in a patient who apparently had no pulmonary symptoms.

Case II Another patient, No 59663-30, autopsy No 8734-30, a man, age 52 years, was admitted to Kings County Hospital and died forty-eight hours later. He was extremely pale, was struggling for air, and had been drinking large quantities of whiskey for more than a month. He was a chronic alcoholic. His condition was critical on admission. His blood pressure was 80/60. He became unconscious shortly after entering the hospital but could be aroused. His red blood cells were 1,060,000 and his hemoglobin was 35 per cent. A history obtained from his family reported a gastric hemorrhage and bloody stools about one month before admission. He complained of pain in the abdomen. The patient did not show emaciation. During his short stay in the hospital, he was restless and fighting for air. There were many coarse, moist râles throughout both lungs. The object of treatment of this patient was to support and stimulate him over the emergency. However, he died forty-eight hours after admission. Our feeling was that he had a severe anemia, a chronic alcoholism, with an alcoholic wet brain. A post-mortem examination was permitted, of which the points of interest to us now are: "The right lung shows infarcted areas at the base, which are well circumscribed, and adjacent to this is

found a cavity from which pus escapes. At about the centre of the middle lobe, there is a tumor-like mass, five and one-half centimeters in diameter. This mass is firm, nodular and white in color. The pleural surface of the left lung is thickened and rough. On section, a frothy fluid can be expressed from the cut surfaces. The ribs and vertebrae have tumor-like growths. The diaphragm, also, shows raised nodular masses which are hard. There is no gross pathology of the trachea or esophagus. The mucosa of the stomach near the pyloric end and the duodenum show denuded areas suggestive of old ulcer formation, the remainder of the gastro-intestinal tract is grossly normal. Histologically, the patient showed acute purulent bronchitis, pulmonary abscess, confluent broncho-pneumonia, metastatic lymphosarcoma in the lung, lymphosarcoma of the peribronchial glands, metastatic lymphosarcoma of the bones and chronic ulcer of the duodenum. Here we have another patient upon whom the diagnosis of malignant tumor in the lung could not be made because of his condition on admission to the hospital. Ewing,⁶ in his book on Neoplastic Diseases, states that "frequently these new growths are discovered only at autopsy." Adler⁵ states "one form that occurs occasionally is that of a single nodule, usually quite small surrounded perhaps by a few minute malignant nodules deeply buried in the lung tissue of one lobe, producing only very slight or possibly no symptoms during life, and as a rule, discovered by mere accident at autopsy."

There are some patients upon whom the diagnosis of malignant tumor in the lung is not difficult to make.

Case III A young man, No 56734-30, a laborer, 21 years old, was admitted to Kings County Hospital, August 13, 1930, with the following complaints: Weakness, pain in the chest and in the abdomen, and loss of thirty pounds weight in six months. On January 10, 1930, the patient was operated upon for hernia complicated by an undescended testicle, and a varicocele operation was performed. On July 27, 1930, at Kings County Hospital, his left testicle was removed. Following this operation, he had pain almost contin-

uously in the abdomen and in the flanks. One week before admission, on August 13th, pain appeared in the lower part of the chest on both sides. Upon auscultation, the patient had numerous râles throughout the left lower lobe, and râles below the scapula on the right side. There was a lump at the upper angle of the scar of the operation on the testicle.

A résumé of the radiographic reports follows. Numerous well defined nodular metastases are strewn throughout both lungs, these nodules varying from approximately 1 to 4 cm in diameter, being definitely spherical, borders well defined, these are more commonly situated near the periphery. Osseous system examination fails to reveal any evidence of abnormality of texture of the bones of the skull, extremities or trunk. Conclusions. Nodular type of pulmonary metastases, probably the result of sarcomatous infiltration. (See figure 1.)

This man died October 26, 1930, seventy-four days after admission to the hospital and ninety-one days after removal of the testicle. The diagnosis with this patient was not difficult, as the pathological report from the section of removed testicle is as follows: "The section shows testicle and epididymis. The testicular portion shows no marked change from the normal. The epididymis, however, presents a neoplasm composed of varying types of cells, some being large and round, some showing eccentric nuclei and rather horse-shoe shaped, and still others showing cells not unlike those known as the reticulum cells of lymph nodes. Hyperchromatism is quite a marked feature. There are numerous areas of necrosis. The neoplasm is definitely histoid in morphology. The diagnosis of the tumor is polymorphocellular sarcoma." With this young man, it was not difficult to make a diagnosis of metastatic sarcoma in the lungs.

Case IV Another type of patient, No 24877-29, Autopsy No 7796-29, admitted to the Kings County Hospital, was a woman forty-seven years old, who complained of pain in the chest, weakness, loss of weight and dyspnea. This patient died seven days after admission to the hospital. She had had a breast amputated six months previously for carcinoma. The autopsy revealed metastases

to the lungs, heart, liver, adrenals and mesentery. A diagnosis, before death, of metastatic carcinoma in the lung was not difficult.

Although we know many times that we have a metastatic tumor in the lungs from a primary malignant growth elsewhere in the body, the classification of the type of tumor is not always as easy a matter as in the two preceding patients.

Case V A man, No 5989-28, Autopsy No 7291-28, forty-six years old, was admitted to Kings County Hospital complaining of pain localized in the right chest and upper abdomen about the costal margin, and included between the anterior and posterior axillary lines. This pain had persisted for two weeks and was described as if needles were sticking into him. The patient stated that at the onset of this attack he had vomited for five days. There was no blood in the vomited material. On admission, the patient did not appear acutely ill but did show signs of emaciation. A slight cough was present. He had signs of fluid in the right pleural cavity. There was marked epigastric and upper rectus rigidity. Later a bloody fluid was removed from the right pleural cavity. The conditions considered as possible were chronic pulmonary tuberculosis, pleural effusion, malignancy in the lung, chronic gall-bladder disease, peptic ulcer and malignancy in the epigastric area. This patient died thirty-one days after admission to the hospital.

A résumé of the radiographic reports follows. Examination of the gastro-intestinal tract fails to reveal any evidence of organic lesion of the stomach, duodenum or intestines. There is moderate enlargement of the liver. Examination of the lungs, eleven days later, reveals a large effusion in the right pleural cavity, with displacement of the mediastinal contents to the left and a localized area of incomplete consolidation at the level of the third left interspace. The only diagnosis warranted on the roentgenograph of the lungs is a localized area of consolidation and a large pleural effusion. The new growth element can only be deduced

FIG 1 Case III Metastatic tumors in the lung Numerous well defined areas of infiltration of the parenchyma of various size, spherical in shape, occupy chiefly the upper lobes particularly about the level of the first and second interspaces anteriorly This is a nodular metastatic neoplastic infiltration from a primary growth in the testicle, diagnosed histologically as embryonal carcinoma

FIG 2 Case IX A large, spherical area of non-aeration approximately 10 cm (film measurement) in diameter, occupies the posterior portion of the upper right lobe. There is no evidence of displacement of the mediastinal contents. There is partial absence of the lateral portion of the second rib probably due to pressure erosion. In pulmonary neoplasm of the primary type in the right upper lobe.

nitely determined by removal of fluid and a re-examination.

The histological findings at autopsy were

Brain Metastatic hypernephroma

Pericardium Metastatic hypernephroma

Lungs. Congestion, edema, anthracosis and metastatic hypernephroma

Right Kidney Hypernephroma

Peritoneum: Metastatic hypernephroma

Vena Cava Metastatic hypernephroma

Case VI Another patient of this type was a woman, No 58893-30, Autopsy No 8704-30, 39 years old, admitted to Kings County Hospital with abnormal pulmonary symptoms, as well as general signs of severe disease. This patient died seven days after admission. A post-mortem examination was made which yielded the following information:

Lungs Metastatic teratoma

Liver Metastatic teratoma

Adrenals Metastatic teratoma

Kidneys. Acute suppurative pyelonephritis

Urinary Bladder Acute gangrenous cystitis

Spinal Dura mater and Posterior Nerve Roots of Upper Lumbar Cord. Metastatic teratoma

Ovary. Primary malignant teratoma

It is not difficult to realize from the histories, that each individual patient with a new growth in the lung can present an interesting problem in diagnosis.

Hamman⁷, of Baltimore, writes "In the lungs, tumor growth may cause cavities, bronchiectasis, erosion of blood vessels, sometimes with fatal hemorrhages, and it may be accompanied by a bronchopneumonia, empyema, abscess or gangrene." He adds, "a small lung tumor that gives no local symptoms may cause widespread metastases, any organ or tissue may harbor metastases, but lymph glands, liver, bones and kidneys are most often invaded." Because of the

variety of the modes of expression of these new growths, the diagnosis of malignant tumor of the lung is not always an easy diagnosis to make.

Case VII A colored man, 46 years old, was admitted to Kings County Hospital and died twenty-five days later. He complained of pain in the right chest, anteriorly, of four months duration, he had a productive cough for six months, with occasionally blood tinged sputum, he had lost thirty-two pounds in weight in five months; he had a marked dyspnea, and complained of extreme weakness. We have presented here the usual symptoms of malignancy of the lung, with the report of a negative Wassermann reaction, and numerous sputum reports negative for tubercle bacilli. He showed signs of serious trouble in the right upper lobe. The radiological report stated: "This is a lobar type of lung tumor in the right upper lobe with degeneration and cavitation."

This patient was presented for bronchoscopy. We received the following comment: "Owing to considerable pus and mucus coming from the right bronchus, and also due to the presence of edema of the same bronchus, the examination was not completed. Two weeks after admission, the patient expectorated a red, bloody sputum. Eight days later, he developed a pneumonia in the right lung and died in three days. Clinically this is a patient with a primary carcinoma of the lung, but in the absence of a post-mortem examination, it is impossible to call it primary."

Case VIII A man, No 19143-26, forty-six years old, was admitted to the Kings County Hospital and died fifty-two days later. This patient stated that for the past nine months he had been unable to work because he had not felt well. There were present as complaints: Cough, pain in the chest on the right side, loss of twenty pounds in weight in six months, general weakness, night sweats and anorexia. The patient appeared acutely ill. His temperature was 101.6°, his pulse was 90 per minute, his respirations were 20 per minute. His breath was foul, his mouth contained many carious teeth, the uvula and pharynx were

injected His chest was of the emphysematous type There was dullness on percussion and tubular breathing over the right upper lobe A few scattered râles were heard over both apices The conditions found suggested a new growth in the right upper lobe The radiographic report stated that the picture was suggestive of new growth in the upper lobe, right side Lipiodol injection revealed none of the mixture in the right upper lobe, probably the result of occlusion of the right bronchus, consequent to a new growth The report of a bronchoscopic examination showed that the trachea was found fixed, and pushed towards the left On the right lateral wall in the region of the fourth or fifth tracheal ring there was a small, irregular granulation-like mass about two millimeters in diameter Because of the fixation of the trachea, entrance into the right main bronchus was difficult At the entrance of the upper lobe bronchus, an irregular mass was encountered and a section was removed for examination Microscopic report of the section taken was epidermoid carcinoma

This patient's urine was normal Numerous sputum examinations were negative for the tubercle bacillus His blood Wassermann was negative His blood chemistry showed the following Urea, 40 mg per 100 cc, creatinin, 12 mg per 100 cc, sugar 105 mg per 100 cc

His blood count showed Red blood cells, 3,360,000, hemoglobin, 70 per cent, white blood cells, 15,100, polymorphonuclears, 80 per cent, small mononuclears, 15 per cent, large mononuclears, 2 per cent, transitionals, 3 per cent, morphology, normal

The following interesting comment is made on the history This is a case of malignant tumor of the lung, carcinoma The question of primary or secondary growth must be left to further study by necropsy Unfortunately it was impossible to obtain a post-mortem examination of this patient

Fortunately with the patient whose history I now present, we were granted permission for a post-mortem examination

Case IX A man, No 55210-30, Autopsy No 8668-30, forty-six years old, was admitted to the writer's service at Kings County Hospital complaining of severe, paroxysmal pain in the right chest for seven weeks, cough productive of a whitish sputum, which was blood tinged on two occasions eight weeks and four weeks before admission, loss of twenty-five pounds in weight in six weeks, cyanosis, marked dyspnea upon slight exertion, anorexia since the onset of pain This patient had always enjoyed good health except for an attack of influenza during the epidemic in 1918—twelve years previously At the time of his admission, the patient was in no acute distress, and did not appear acutely ill There was diminished tactile fremitus over the upper right lobe to the fourth rib Dullness on percussion was present over this area, with cavernous breathing and increased whispered voice transmission There were no râles on cough over this area Tenderness was present along the course of the fourth rib, which was roughened in the anterior axillary line While in the hospital, this patient showed mental symptoms, suggestive of metastases to the brain The blood Wassermann was negative Repeated examinations of the sputum were negative for the tubercle bacillus The urine at the time the temperature was 101° showed a trace of albumin, many finely granular and hyaline casts and some leucocytes The blood examination showed red blood cells, 3,468,000, white blood cells, 16,900, polymorphonuclear cells, 75 per cent, small mononuclears, 21 per cent, large mononuclears, 1 per cent, transitionals, 2 per cent, eosinophiles 1 per cent, hemoglobin, 70 per cent

A resumé of the radiographic reports states There is complete consolidation of the upper portion of the right lung the lower level of which is noted at the level of the fourth rib anteriorly, the lower border of this consolidated area is convex downward, the remainder of this lung and the left present no evidence of pathological changes Conclusions—the findings are indicative of pulmonary neoplasm of the upper lobe, right

This patient died nineteen days after admission

FIG 3 Case X Primary carcinoma of the lower lobe of left lung Consolidation extends almost to the periphery laterally

FIG 4 Case X Primary carcinoma of the lung Bronchography Complete ob-
struction of the lower left bronchus supplying the inner half of the lower lobe

The post-mortem findings were Carcinoma of the lung, primary, right side, congestion of the liver and the spleen, cloudy swelling of the kidneys, congestion and edema of the lungs

Peritoneal Cavity No free fluid, no adhesions

Right Lung Densely adherent to the parietal wall, especially the upper lobe, stripped away with difficulty. There was marked erosion of the 2nd, 3rd and 4th ribs in the mid-axillary line. On section, the upper lobe was found to be filled with a grayish firm tumor mass, in the central portion of which there was a large cavity filled with a reddish cloudy fluid. The lower lobes were dark red and congested, but showed no evidence of tumor.

Left Lung There was some congestion and edema at the base, no enlargement of the mediastinal glands.

Pericardium No free fluid, no adhesions

Histological examination of the lungs showed the presence of a tumor composed of interlacing islands of squamous cells, and here and there occasional attempts at pearl formation. The histologic picture was one of typical epidermoid or squamous-celled carcinoma, and in view of the fact that no other primary focus was observed at autopsy, it is probable that this was an example of primary epidermoid carcinoma of lung, possibly metaplastic. (See figure 2)

Case X Another patient, on the writer's service at the Kings County Hospital, admitted June 18, 1930, was a man, Case No 64670-30, Autopsy No 8831-30, forty-five years old. The patient had noticed for the past year weakness, loss of weight and cough. He had pain in the left chest and shoulder for the past three months, also extreme dyspnea. Physical examination was suggestive of new growth in the left lower lobe, with possibly pleural effusion. No fluid was ever obtained from the pleural cavity. On admission, his blood counts did not show a secondary anemia, his leucocytes were 10,150. An anemia developed later. His blood chemistry was normal. His urine showed a low specific gravity, 1012, a faint trace of albumin, a few hyaline and finely granular casts. The patient remained

in the hospital 152 days before death, expectorated much bloody sputum, had much pain in left lower chest and lost much weight. A résumé of the radiographic report, states: Examination of June 19th, the day following his admission, reveals an irregular area of consolidation occupying the inner and posterior portions of the lower left lobe. No evidence of other pulmonary or pleural pathological changes noted. Approximately one month later, this area of consolidation of the lower lobe, left, is noted to be increased, extending almost to the lateral periphery. (See figure 3)

One week later, bronchography was done by the passive method, at which time there was noted a complete obstruction of the lower bronchus, left, supplying the inner half of the lower lobe (figures 4 and 4A). The occlusion of this bronchus was complete. The remainder of the bronchi extending from the lower main stem were noted to be of moderate size, usual contour and distribution.

Diagnosis New growth, bronchogenic type, of the lower lobe, left

A bronchoscopic examination made July 31st, 1930, revealed a hard mass obstructing the left main bronchus in the region of the left lower lobe. A specimen of this mass was obtained for examination. A second bronchoscopic examination was made two weeks later, with the findings similar to those of the first examination. The histological report of the biopsy specimen, examined by Doctor Hala, was as follows: The section is one of new growth composed of irregular islands of epithelial cells of the types which are encountered in the two lower layers of the epidermis. The remainder of the section consists of a fibrous stroma with here and there small mucous glands of normal appearance. **Diagnosis** Epidermoid carcinoma.

The post-mortem examination revealed. Emaciation, carcinoma of the lung with involvement of the left bronchus and lower six ribs and dorsal vertebrae, cystic adenoma of the thyroid gland, cloudy swelling of the myocardium, congestion and edema of the lungs, chronic splenitis, moderate passive congestion of the liver, acute nephrosis, atheroma of the aorta, cysts of the adrenals,

adipositas of the pancreas, bronchopneumonia, bilateral pleuritis

At the lower left bronchus, there was found a tumor-like mass with involvement of the left lower lobe throughout. The thyroid was somewhat smaller than normal, on section, the architecture was somewhat distorted and had a shiny appearance. The centre of each lobe was cystic. The lungs were dark gray in color. The pleurae were thickened and adherent throughout both cavities. In the lower left portion of the chest, a tumor-like mass about the size of a grapefruit was found, involving the ribs and vertebrae. These were somewhat soft, friable and undergoing rarefaction. The lungs had a shotty feel throughout. The left lower lobe was entirely made up of tumor and was adherent to the diaphragm. In areas, it was firm, and on section, presented a white, glistly appearance. In other portions of the lung, the appearance was ragged and moth-eaten. The right lung exuded a frothy fluid from the cut surfaces.

The histological data were as follows:

Bronchus The mucosa was absent, and replaced by a tumor consisting of connective tissue stroma and incorporating numerous and irregular islands of epidermal cells.

Left Lung The section showed the presence of a neoplasm which was similar in architecture to that observed in the wall of the bronchus, consisting of numerous islands of epidermal neoplastic cells. There was but little attempt at ultimate differentiation in the tumor cells. In only one area could there be observed an attempt to form an epithelial pearl.

Diaphragm Attached to the diaphragm was a rather large nodule of tumor which in structure resembled that already described in the bronchus.

Aorta Atherosclerosis. The adventitia of the aorta was invaded by nests of epidermal neoplastic cells.

This is evidently a case of primary carcinoma of the lung, originating in the left bronchus. The tumor is definitely of epidermoid structure.

The following history is of interest because it was read at the meeting of

the Brooklyn Society of Internal Medicine on November 28, 1930, as that of a patient with a carcinoma of the lung which we believed to be primary in the lung. This patient died November 28, 1930, and an autopsy was permitted which proved that the carcinoma was primary in the lung.

Case XI A man, Case No 65352-30, Autopsy No 8846-30, 50 years old, was admitted to Kings County Hospital July 28, 1930, and died November 28, 1930, after one hundred and twenty-three days in the hospital. He complained of pain in the left chest, cough with expectoration, which was never bloody, weakness, loss of weight and anorexia. These symptoms had been more noticeable during six weeks before admission, although the patient had given up his business, six months previously.

Examination showed the presence of a new growth in the left lung. No masses were found in the abdomen. There were no enlarged glands present. A rectal examination showed no prostatic enlargement. On November 1st, the patient developed a consolidation of the right upper lobe. During the latter part of the patient's stay in the hospital, his expectoration became more profuse and more foul. Three days before death, the following note was made: "The patient coughs considerably and raises much sputum, he has some change in his voice sound. There is a sigh with each breath, which has a laryngeal quality. He is suffering considerable pain, and has been getting progressively worse." Hemoptysis was never present during his stay in the hospital. Repeated examinations of his sputum were negative for the tubercle bacillus. His blood Wassermann was negative. His urine showed the following:

Specific gravity, 1012, faint trace of albumin, occasional hyaline casts. Blood Chemistry—Urea, 20 mg per 100 cc of blood, creatinin, 1.1 mg per 100 cc, sugar, 100 mg per 100 cc.

His blood on admission was: Red blood cells, 4,448,000, white blood cells 5700 polymorphonuclear cells 68 per cent.

FIG. 4A. Case X. Bronchography. Primary carcinoma of lower left bronchus
Oblique position

FIG 5 Case X A bronchogenic tumor whose origin is just at the bronchial bifurcation (see arrow) At A are seen secondary tumor masses in the pulmonary parenchyma

hemoglobin, 80 per cent, morphology, normal

A résumé of the radiographic reports states There is a slight decrease of aeration of practically the entire upper lobe, left, with a moderately large mass of irregular contour at the left hilus. In the posterior portion of the lower lobe is seen a horizontal fluid level, which is indicative of a partially filled abscess cavity. Examination of the osseous system at this time revealed no tumor growths in the bones. Examination three months later revealed no further decrease of aeration of the upper lobe, left, and a partial decrease in the lower lobe, the mass at the hilus has increased in size and in its outer portion is an irregular area of re-aeration indicative of partial destruction (degeneration) of this process. Conclusions: A primary new growth of bronchogenic type with partial obstruction to the aeration of the left upper lobe and infection with abscess cavitation in the left lower lobe as described, and probable degeneration of the neoplastic mass in the upper lobe.

A report of the bronchoscopic examination follows. Direct laryngeal examination reveals a complete paralysis of the left vocal cord with partial involvement and limitation of the right vocal cord. Examination of the bronchi reveals an extensive growth involving the left main bronchus, including the corina and extending to the right bronchus (posterior left lateral aspect). A specimen of the tumor was taken for microscopic study. The report upon this specimen is that "this section shows a portion of tumor growth which is composed of numerous islands of squamous epithelial cells. Mitotic figures are present. Diagnosis: epidermoid carcinoma."

Upon the death of the patient, permission was obtained to perform a post-mortem examination, which revealed

Primary carcinoma of the left lung with involvement of the lower six ribs on the left side and the corresponding vertebrae, acute nephrosis, vascular nephritis, chronic myocarditis, congestion and edema of the lungs, bilateral pleuritis, abscess of the lung, left, moderate passive congestion of the liver, acute splenitis, general arteriosclerosis, adiposis of the pancreas, emaciation

The body was that of an elderly male about fifty-five years old, rigor present, lividity absent, emaciated and dehydrated with the supra- and infra-clavicular depressions marked.

Upon removal of the sternum marked bilateral pleuritic adhesions were found. The omentum was attached in the gall-bladder region beneath the liver. The left lung adhered to the posterior wall of the thorax especially in the region of the lower six ribs and corresponding vertebrae. The lung was freed and a solid tumor mass was found involving the lower lobe in its posterior aspect, and in the anterior aspect, an abscess cavity was noted. The corresponding ribs and vertebrae showed rarefaction of bone. The right lung was rather shotty on palpation. The pleura was thickened, and on section, a small amount of frothy fluid could be expressed. No tumor could be noted in the right lung, but the peribronchial lymph glands were markedly enlarged, and also, extending down from the bifurcation of the bronchus, a tumor-like mass was noted having a fungus-like appearance. The entire left lung showed consolidation except at the upper portion of the lower lobe which contained an abscess cavity about the size of a lemon. Dissection of the bronchus of the left side shows neoplastic infiltration which began about 0.75 cm above the bifurcation and continued down about 2.5 cm into the left bronchus. At the terminus of the bronchus on the left side, was an abscess cavity. The lung on section showed this circumscribed cavity, and also a tumor-like mass involving the upper and lower lobes, with thickening of the pleura.

Histological data —

Heart Marked adiposis, cloudy swelling of myocardium

Lungs Epidermoid carcinoma. The tumor cells, in general, are squamous in morphology and are surrounded by fibroblastic tissue. The section incorporates part of the bronchus which latter shows evidently the primary focus.

Liver Cloudy swelling, moderate chronic passive congestion

Spleen Congestion and edema

Adrenals Cloudy swelling, congestion and edema of medullae
 Pancreas Moderate adiposis
 Kidneys Cloudy swelling
 Aorta Calcification of media

Cause of Death Primary carcinoma of the lung, with involvement of the lower six ribs and corresponding vertebrae

On January 24, 1931, a short time before the preceding section of this paper was prepared, a patient, M N, a woman 52 years old was admitted to Kings County Hospital with the following complaints—Cough of four months' duration, with slight expectoration, not bloody, pain in the left chest, loss of weight, fourteen pounds in four months, dyspnea, of two months' duration, increasing in severity, no night sweats

One month before admission, the patient developed what she called a "fresh cold," which persisted. For the past two months, the patient slept only on the left side because of increase in cough and dyspnea in any other position. On admission, the patient was not emaciated, did not appear acutely ill, was not suffering severe pain, but had a marked dyspnea

Physical examination revealed the signs of an effusion in the left pleural cavity and, possibly because of the recent review of the subject, the resident physician made the additional diagnosis of malignancy in the lung

Thoracentesis was performed twice, five days after admission, 1500 cc of a clear, serous fluid was withdrawn, and eleven days after admission 1250 cc of a dark amber fluid. Both fluids under the microscope showed many red blood cells and were transudates

Examination of the blood on admission showed

Red blood cells, 3,808,000, white blood cells, 12,200, polymorphonuclear cells, 70%, small mononuclear cells, 25%, large mononuclear cells, 3%, transitional cells, 1%, eosinophilic cells, 1%, hemoglobin, 80%

Blood Chemistry—Urea, 30 mg per 100 cc of blood, creatinin, 12 mg per 100 cc, sugar, 145 mg per 100 cc

Examination of the urine showed no abnormalities. Sputum examination was negative for the tubercle bacillus. Blood Wassermann was negative. Six days after ad-

mission, blood streaked sputum was present and there was a sharp rise in temperature. During the stay in the hospital, the temperature varied between 99.8° and 104.4° and never became normal. The dyspnea increased in severity, cyanosis was marked and the patient showed an increasing heart impairment. On the seventeenth day in the hospital, an erysipelas developed on the left side of the head and face, the temperature rose to 103°, the pulse to 124, and the respiration became 32. Signs of a bronchopneumonia were present. Radiographic reports taken on admission and later were "massive effusion of the pleural cavity." Twenty-one days after admission, the patient died, apparently from cardiac involvement

The findings on post-mortem examination were unusually instructive. They revealed

Congestion and edema of the lungs, bronchopneumonia, primary bronchogenic carcinoma on the left side, bilateral pleuritis, chronic myocarditis, atheroma of the aorta, acute and chronic pericarditis, passive congestion of the liver, septic spleen, chronic vascular nephritis, degenerated adrenal, chronic fibrotic oophoritis

Marked bilateral pleural adhesions were found. In the left thoracic cavity about 100 cc of cloudy, gray, thin fluid was present, and a fresh, fibrinous plastic exudate surrounded the entire lung and upper surface of the diaphragm. The right cavity showed a similar plastic exudate and a moderate amount of transudate fluid also. The pericardium was adherent to the left lung and occupied about twice the normal space in the mediastinum. The lungs weighed 1800 gms

The left lung was of a grayish white color. A firm, tumor-like mass had invaded the lower portion of the upper lobe and the major portion of the lower lobe and in an area about the diameter of a silver dollar had extended into the visceral pleura. The trachea and bronchi which were dissected out with the lungs were incised and inspected and the tumor-like growth found to have begun, apparently about one-half inch below the bifurcation in the left bronchus, showing a line of demarcation which was pale, anemic and irregular

FIG. 6 Case X A primary carcinoma of the lung of the epidermoid type with origin just at the tracheal bifurcation, (see figure 5) At the right is seen the lumen of a normal bronchiole

FIG 7 Case XI Primary bronchogenic carcinoma of left lung

trast to the normal tissue. The left lung on section, presented a pale, grayish growth, indurated in character and occupying the portions of the lobes above mentioned. The peribronchial lymph nodes were also involved, being enlarged, firm and fibrous.

The right lung was dark gray in color with no apparent metastases. On section, there was a patchy consolidation in the lower lobe showing grayish, granular areas. A frothy fluid could be expressed from the other lobes. The pericardium was thickened and adherent to the left lung, also to the epicardial surface giving the appearance of "bread and butter," the *cor villorum* or *hirsutum*, especially over the left ventricle. In the region of the right ventricle, old fibrinous strands were present. The visceral layer of the pericardium was hemorrhagic and injected.

The heart was markedly enlarged, weighing 600 gms. The ventricular walls were thinned out and of light brown color. On section, fibrosis was present in the musculature. The mitral leaflets were somewhat thickened along their free borders, the aorta showed raised atheromatous plaques, the coronaries were narrowed.

The cause of death was Primary bronchogenic carcinoma of the left lung.

Histological examination confirmed the findings of primary carcinoma of the lung, together with bronchopneumonia, acute seropurulent epicarditis, chronic fibroblastic pericarditis, acute seropurulent pericarditis, facial erysipelas.

It is a privilege to present here for the first time, the histories of five patients with primary carcinoma of the lung proven by autopsy. These five, together with the three reported in detail by the writer⁸, in 1925, make a series of eight cases of primary carcinoma of the lung at the Kings County Hospital since February, 1924, three in 1924, and one in 1927, and the four last mentioned within the past six months. We feel that a number diagnosed as carcinoma of the lung, upon which no autopsies were permitted,

were primary growths in the lung, the four patients whose histories have just been given were diagnosed as carcinoma before death and the primary condition was proven when post-mortem examination was allowed.

In making a diagnosis, the following steps are taken. The history, the physical findings, the course of the disease, and as at the time of Graves' lecture, the gross findings of tumor at autopsy. To these findings have been added

- (1) The fluoroscopic examination and the roentgen ray picture,
- (2) The bronchoscopic examination and the microscopic examination of the specimen obtained during life,
- (3) The histological findings at autopsy.

The use of the bronchoscope has been of inestimable value as an adjunct in diagnosing these malignant conditions.

"The value of bronchoscopy in diagnosis is primarily dependent on data obtained by direct visual inspection. It must be remembered, however, that in a diagnosis of pulmonary disease, the entire lungs are not open to inspection. Only the larger bronchi can be examined. The minute branches cannot be inspected by any endoscopic means. However, secretion can be observed coming from the orifices of the small branches and uncontaminated specimens of this can be removed for bacteriological study. Positive findings are of the utmost value. Bronchoscopy is indicated when there is a diagnostic question remaining after physical examination, radiographic studies and laboratory investigations have been carried out⁹."

In reviewing eighty-one histories of patients at the Kings County Hospital, presenting evidence of malignant tumors in the lung, the writer found pa-

tients who may be classified as follows

Eight with primary carcinoma in the lung

Thirty-five with what is believed to be carcinoma in the lung, without autopsy, and not metastatic from other organs

Twenty with metastatic carcinoma in the lung

Ten with metastatic lymphosarcoma

Six with metastatic sarcoma

One with metastatic hypernephroma

One with metastatic teratoma

Primary sarcoma in the lung is rare. Carcinoma is the commonest tumor in the lung, whether primary or secondary. These secondary growths may occur by direct extension from contiguous carcinomata, or as metastases from distant tumors. Pleural effusion is usually the first evidence of direct invasion from the breast or the stomach. Of carcinomata that metastasize to the lung, breast and kidney tumors are clinically the most important. These metastases are frequently small, and even though they may be numerous, they may cause few pulmonary symptoms, and are usually overlooked clinically. Occasionally miliary carcinomatosis of the lung occurs. The association of obscure or unusual pulmonary symptoms and signs with one or more nodules in the bones is peculiarly characteristic of hypernephroma, although it may be present in sarcoma.

From the histological viewpoint three types of pulmonary carcinoma are recognized, arising respectively from the bronchial epithelium, the

bronchial mucous glands, and the alveolar epithelium. In other words, they may be bronchogenic or parenchymal.

Carcinoma arising from the bronchial epithelium often causes bronchial obstruction and bronchiectatic cavities, it seldom causes a diffuse tumor of the lung.

Carcinoma arising from the mucous glands begins in the large bronchi. A number of small growths have been described of glandular structure with mucous secretion beginning in the walls of the bronchi, and covered by intact bronchial epithelium. These typical mucous gland tumors infiltrate the bronchial wall, often causing bronchial obstruction. As the tumor spreads by direct growth and by metastasis, the characteristic gross and histological picture may become obscured. The secretion of abundant mucus is a very characteristic feature of mucous gland growths, although it is not restricted to them.

Carcinoma arising from the alveolar epithelium produces infiltrating masses which often spread rapidly, involving a lobe or larger areas, and somewhat resemble organizing pneumonic consolidation. At times, instead of a diffuse growth, multiple nodular tumors are formed.

Secondary sarcoma of the lung is less common than secondary carcinoma, although melanotic sarcoma and sarcoma of the bone almost always metastasize to the lungs. Pulmonary lympho-sarcoma must always be secondary to tumors arising in lymph glands or in the thymus.

"General weakness is a frequent complaint, often an initial one, and tends to increase as the disease progresses but without

FIG 8 Case XI Primary carcinoma of the lung This neoplasm is bronchogenic in origin and its focus can be seen readily at the bifurcation of the trachea just above A The mucosa of both bronchi is infiltrated for some distance below the bifurcation and at A the tumor has advanced into and through the bronchial wall Secondary nodules are exhibited at B The arrow points to a large bronchiectatic cavity There is considerable thickening and invasion of the visceral pleura at C

FIG 9 Case XI Primary carcinoma of the lung This section shows an epidermoid type of growth in the lung parenchyma There is considerable fibroblastic stroma The primary growth in this case is illustrated in figure 8

ing is by no means a constant occurrence in malignancy of the lung. In some patients, however, the onset of manifest symptoms is slow and insidious. In a number of patients, the first serious manifestation of disease occurs with comparative suddenness. The patient may seek the physician

(1) primarily on account of hemoptysis, the cause of which has either not been determined, or has been thought erroneously to be tuberculosis of the lungs,

(2) because of evidences of pleurisy with or without effusion,

(3) those whose history and physical examination suggest the presence of a localized infection within the chest,

(4) those suffering from grave disability and showing the more obvious phenomena which characterize the later stages of intrathoracic malignant disease".⁵

In regard to the presence of pleurisy, we feel that the commonest cause of pleurisy in the young adult is tuberculosis. We also feel that we must always keep in mind that the occurrence of an unexplained pleurisy, especially of a pleurisy with effusion, in a patient of middle age or later, should suggest the question of the presence of new growth in the lung or mediastinum. If the effusion is bloody, it may be regarded as almost pathognomonic of malignant disease in the lung or pleura. The presence of tubercle bacilli in the sputum does not exclude malignancy of the lung, which may co-exist with pulmonary tuberculosis. A malignant tumor may be present in the lung of a patient having syphilis, and one has to make a differential diagnosis between gumma of the lung and a non-syphilitic tumor.

No brief description of the physical signs can be given. These must differ according to the type of the disease, the site of the tumor, the extent of lung involved, and the presence or ab-

sence of effusion in the pleural cavity.

As we may see from the histories of these patients, the commonest signs and symptoms are

Cough with or without expectoration, which, if present, may be bloody

Hemoptysis,

Dyspnea—very severe in some cases,

Pain—which may be steady or paroxysmal,

Cyanosis,

Weakness,

Emaciation—which is not always present,

Gastric symptoms—which may be present but are not common,

Fever—which may be present in moderate degree, due to secondary illness

What may we consider the prognosis in these patients with malignancy of the lungs? The general rule in all malignancy—"the earlier in life that the growth appears, the more malignant it will be," seems at present to be our answer.

The mode of death may vary in different individuals. There may be a gradual general failure. Death may result from sudden, large hemorrhage, this is considered rare. The patient may have a hemiplegia due to metastasis lodging in one of the cerebral vessels and causing embolism. He may lapse into coma due to a growth in the brain tissue, more often the coma is due to a toxic state, with a general septic absorption. There may be sudden and distressing dyspnea with death.

What should be our feelings concerning the treatment and the results

of treatment in these severe conditions? When one considers that the treatment of malignancy seems now as hopeless as did the treatment of pernicious anemia when many of us began the study of medicine, we should be hopeful of developing a cure in malignancy. How wonderfully, indeed, has the prognosis in pernicious anemia been changed by the use of liver and defatted stomach in treatment^{10,11}. Surely, we must be encouraged, also, by the advance in the methods of treatment of many of the scourges of the world, such as the use of quinine as a specific in malaria, the vaccine for small-pox, antitoxin for diphtheria, anti-tetanic serum in the prevention of tetanus, typhoid and paratyphoid vaccine in the prevention of typhoid and paratyphoid fevers, and meningococcic serum in the treatment of meningococcic meningitis. Something must and will be found to combat successfully every malignancy wherever it may be found in the body. The surgeons feel that surgery may be of benefit where it is possible to discover the condition early. Electrical treatment, and possibly radium, may be the means by which this seemingly hopeless problem will be solved. The cure may be accomplished before the cause of malignancy is discovered.

I wish to acknowledge here my appreciation to my colleagues at the Kings County Hospital in all departments of the Hospital for the cordial co-operation accorded to me in reviewing this work. Doctor Rendich, Director of the Radiographic Service, has kindly read the radiographic pictures, and Doctor Hala, Director of the Pathological Service, has kindly translated the pathological slides, the Record Room Service has been invaluable in correlating this review.

Without this co-operation, it would have been impossible to have completed this agreeable task.

SUMMARY

A study of eighty-one patients with malignant tumors in the lung presented —

Eight with primary carcinoma in the lung, confirmed by autopsy,

Thirty-five believed to be carcinoma in the lung, the diagnosis having been made on the history, physical examination, radiographic findings and bronchoscopy with biopsy specimen but without autopsy,

Twenty with metastatic carcinoma in the lung from a primary focus elsewhere,

Ten with metastatic lymphosarcoma in the lung,

Six with metastatic sarcoma in the lung,

One with metastatic hypernephroma in the lung,

One with metastatic teratoma in the lung,

It has been possible to demonstrate and illustrate in this paper every step in arriving at the diagnosis of primary carcinoma in the lung.

Of the eight primary carcinomas in the lung, all were found to be unilateral, with four involving the right lung and four involving the left lung. The symptoms presented by these eighty-one patients varied according to the stage of the disease, the type of tumor, the site of the tumor, the amount of lung tissue involved, and the presence or absence of effusion in the pleural cavity. The commonest symptoms were cough, with or without expectoration, which, if present, was usually bloody at some period of the

FIG 10 Case XI Primary carcinoma of the lung This tumor is definitely adenomatous in architecture as is well shown at A This is a type which is bronchogenic in origin and undoubtedly derived from the submucosal glands of a bronchus In the lower part of A, the cylindric epithelium is well demonstrated The growth has a tendency to be papillated at B Edematous alveoli are found at C, and compensatory emphysema at D

FIG 11 Adenomatoid changes in the lung This section is from a patient having pulmonary syphilis and illustrates the possibility of neoplasia secondary to a luetic lesion. A group of gland-like spaces is seen at A. They are lined by cubical cells. At B is a small miliary gumma, while fibroblastic tissue (an example of the productive inflammation unfailingly observed in lues) can be seen at C.

disease; dyspnea, pain, cyanosis, weakness, emaciation. Hemoptysis was present in those patients having blood vessels involved in the tumor, with ulceration. Fever may be present in the early stages in the presence of a pneumonitis which is usually diagnosed as an atypical pneumonia which does not resolve completely, in the later stages, fever is present because of an inflammatory process in and about the tumor. Abstracts of the histories of eleven patients are given, illustrating these conditions. The post-mortem findings are reported with nine of these histories.

Secondary growths in the lung show an advanced condition of malignancy in the body, and although electric treatment may ameliorate the symptoms and prolong the patient's life, not a great amount of benefit is believed to result from the present treatment of these secondary conditions.

In primary cancer of the lung, in order to diagnose the condition earlier than is usually done, it is necessary that we concentrate our attention (1) upon those patients who complain of persistent cough without demonstrable causes; (2) upon those patients who expectorate bloody sputum at intervals, with no tubercle bacillus in the sputum, (3) upon those patients who complain of general weakness, loss of weight, and do not react to the usual methods of treatment. The value of post-mortem examinations is demonstrated here, and our constant effort should be to obtain permission for more of these examinations. We must be hopeful in the not too distant future for cure of these malignant conditions, as the slight benefit from electrotherapy may be the forerunner of methods to inhibit and stop the destruction of life by these "outlaw" growths.

The Dietetic Treatment of Tuberculosis*†

By ERNEST S. MARIETTE, M.D., F.A.C.P., *Oak Terrace, Minnesota*

IN a previous article the writer has discussed this subject from the administrative standpoint. This discussion will include a broad outline of early history of food supply and diets and its effect upon early medical opinion in the attempt to show how these factors have influenced man's ideas concerning the importance of diet in tuberculosis. While there is still a wide difference of opinion as to the most valuable diet in tuberculosis, an attempt will be made to outline a sane and reasonable basis for the diet used at Glen Lake Sanatorium. Although it is realized that an improvement in nutrition alone may have no effect on the tuberculous lesion, we still believe that every effort should be made to improve the nutrition of the patient, so that his resistance to infection in general may be increased and his sense of well-being improved.

The importance of diet in the treatment of tuberculosis has as its background all of the weight of economic and medical history. Until comparatively recent times the common man has suffered from an unsatisfied hunger. For instance, in the times of the Greeks and the Romans a three pound

mullet cost the equivalent of seventy to eighty dollars in today's money, and at one time Domitian ordered a special session of the Senate to determine the best way to cook a turbot. Surely ancient man loved his food and its palatability was of great importance to him. In the time of Queen Elizabeth only about one-half of the common men had fresh meat as often as once a week and the other half never tasted it at all, and in the time of Louis XV a pound of sugar cost sixty to eighty francs. Therefore, about all that was available for the poor man was bread, peas, soup, bark of trees and certain raw vegetables which are now recognized as very important articles of diet but which were formerly scorned by the wealthy man because of their low cost and common use. These raw vegetables were also believed to be indigestible and harmful "if not by doctor's prescription or their evils lessened by cooking." The medieval cuisine consisted chiefly of soup and soup meats and the exceptions to this rule were few.

Man's struggle for his bite to eat must have made an indelible impression on his mind. He was often tired, hungry and thin and if by chance he secured an adequate amount of food he immediately felt well and strong again. This fact, together with

*From Glen Lake Sanatorium, Oak Terrace, Minnesota, and the Department of Medicine, Medical School, University of Minnesota.

†Received for publication, April 30, 1931.

the fact that man's diet has varied with the locality, the climate and the soil, and the proximity to large bodies of water without any markedly different effect upon his mental or physical development must have indicated to the physicians, at least, that the quantity of food was of much more importance than its character.

Early medicine developed about the diet and the care of the gastrointestinal tract and the patient "went to the same professor for physic and food" Therefore, it was only natural that Hippocrates, Galen, Morten, Reed, Bayle, Laennec and numerous other physicians and writers should all stress the importance of diet in the treatment of any disease such as tuberculosis which is characterized by loss of weight and strength. So much attention was paid to the palatability of the food in the hope that the patient's appetite would be stimulated and thus compensate for the loss of weight, that "a culinary recipe was often considered a remedial prescription"

While the idea of the importance of diet in the treatment of tuberculosis was based on an inaccurate knowledge as to its cause, nevertheless this apparently logical treatment has become so firmly entrenched in the therapeutics of the professional and lay worlds that many still cling to it. In 1835 Clark called attention to the danger of over-feeding the patient, "by which the stomach and bowels are disordered and a new train of symptoms produced which complicates the case and adds to the patient's distress" He also claims that "abdominal congestion leads to a similar condition of the lungs and under such conditions the

patient's life is in imminent danger" This is an actual paraphrase of a statement made centuries before by Hippocrates. Kramci, Grayzel and Shear say that in the olden literature as reviewed by Wells, DeWitt and Long, cod liver oil is mentioned frequently as having great value in the treatment of tuberculosis. Williams, in the early part of the 19th century, claimed that in his opinion "cod liver oil had done more for tuberculosis than all other measures put together" We now realize that its value is probably due to its vitamin content. Unfortunately some people have such a low fat tolerance that they are unable to use cod liver oil and the vitamin content varies with the quality of the cod liver oil. Even as late as the early part of this century, the treatment of tuberculosis consisted of fresh air and an attempt to over-feed the patient. Instances are on record of patients attempting to consume—and they occasionally actually succeeded—a diet of 5,000-7,000 calories per day with frequently disastrous effects upon the gastrointestinal tract. In 1908, Fisher reported that ninety-five sanatoria located in various parts of the world served a diet of 2,140 to 5,500 calories per day with a protein content of from 60 to 190 grams. Recently, due to a better understanding of the pathology of tuberculosis, the over-feeding of patients has ceased in our larger sanatoria but there are still many physicians who believe that tuberculosis is cured by a high protein diet.

If we couple the economic background of an inadequate food supply with the medical background which is based on the picture of tuberculosis as

it is characterized by the word "consumption", we at once see the reason for the importance of diet in the treatment of tuberculosis

In 1919, McCann applied the modern methods of study of nutritional requirements of man to the dietetic requirements of the tuberculous. As a result of these studies he estimated that the daily energy requirements of the consumptive at absolute bed rest ranged from 1760 to 2640 calories per day. The estimation was founded upon the basal heat production plus additions to the diet in accordance with the amount of fever present. He also called attention to the apparent antagonistic metabolic factors in a disease causing abnormal wasting which should be corrected by a high caloric diet but whose cure lies in pulmonary rest. While such a diet might counteract the wasting, yet the resulting accelerated metabolic rate would increase the pulmonary activity. This is contrary to the aim of the present day treatment. Mayer and Kugelmass estimated that the diet which they consider as ideal for the tuberculous individual would accelerate metabolism thirty-seven per cent and hence interfere with the desired pulmonary rest. McCann and Bari in 1920 concluded that as "the food requirements of tuberculous patients are not large either as regards total energy value or nitrogen content, forced feeding is unnecessary and is probably harmful in the active stages of pulmonary disease. Since protein increases the respiratory exchange in the tuberculous as well as the normals it may be well to limit the protein intake during periods of activity in order to put the lungs at

rest." Therefore, it seems that the ideal diet for the consumptive is one which will enable the individual to maintain normal nutrition and his sense of well-being with a minimum amount of pulmonary activity. McCann believes that this can best be obtained by a diet consisting of sixty to ninety grams of protein with fat up to the limit of digestive capacity and a sufficient amount of carbohydrates to raise the caloric value of the diet to 2500 to 3000 calories per day.

While tuberculosis is distinctly an infectious disease, often accompanied by gastrointestinal and nutritional disturbances, rather than a nutritional one man is still searching for a diet which will improve the patient's chance for recovery. Recently Sauerbruch, Gerson and Herrmannsdorfer announced such a diet. This represents an attempt on the part of Herrmannsdorfer to adapt a diet, previously used with excellent results by Dr. Gerson in the healing of wounds, to the treatment of lupus and later of pulmonary and bone and joint tuberculosis. He aimed to correct the excessive tissue hydration which occurs in tuberculosis by so planning the diet that the sodium chloride content of the urine is reduced to 0.2 to 0.3 grams per day. This is to be done through the substitution of mineralogen, a mixture of inorganic compounds containing 70 per cent of calcium phosphate and lactate for table salt. While mineralogen contains a preponderance of alkali-forming salts the German clinicians claim that its chief value lies in its acid-forming properties. Its chemical composition together with the fact that a number of its con-

stituents are absorbed so slightly in the alimentary canal that they can have very little if any effect upon the acid-base equilibrium, makes this contention very doubtful

The diet permits fifty calories per kilogram weight per day with an average maximum of 3500 calories in the ratio of protein 15, fat 17 and carbohydrate 37. This gives a protein allowance of 92 grams per day which the Europeans consider low but which we do not, as the diet in the average American sanatorium consists of 70 to 100 grams of protein. The fat content of this diet is relatively high and the carbohydrate content relatively low because carbohydrates reduce resistance to infection in general. The chief sources of protein are milk and eggs and milled products, as only 500 grams of fresh meat are permitted weekly.

One of the outstanding features of this diet is a relatively large amount of vitamins from A to G inclusive. Fruits and vegetables, either fresh or cooked, which are abundant in vitamins, are used freely as is phosphorated cod liver oil, a teaspoonful of which is given with each meal. The list of restricted and permitted foods is long and has been given elsewhere, so it will be omitted from this discussion. Every attempt, however, is made to improve the palatability of the food and to compensate for the lack of its salt. In Munich the results of this diet have apparently been extremely beneficial in lupus but not so beneficial in bone and joint tuberculosis and its value in the treatment of pulmonary tuberculosis has not been so easily determined.

Mayer and Kugelmass' report on twenty patients at Saranac Lake who failed to gain on the accepted therapy over a period of two or three years previous to the use of this diet is very interesting. On this diet the symptoms improved, there was partial x-ray clearing in about a third of the cases but the sputum remained positive in all cases. Two very stubborn cases of intestinal tuberculosis cleared up clinically and x-ray filling defects of the colon disappeared. The results obtained were in general accord with those obtained in similar studies made on rats maintained on an acid forming and base forming diet respectively. Clarence Emerson, of the Lincoln General Hospital, reports favorably on a series of ten patients treated with this diet over a period of twelve months. While he is apparently not unduly enthusiastic about it, still he believes that this diet favors an improvement in tuberculosis. Martin, on the other hand, believes that one should strive for a slight alkalosis of the blood and tissues rather than for an acidosis, while Von Baeyer reports that his tuberculous patients thrive on a dry diet.

Myers stresses vitamin A particularly, while McConkey and Smith believe that all vitamins are of extreme importance in tuberculosis and other chronic infections. McConkey reports that the healing of intestinal ulcers is markedly improved through the administration of cod liver oil and tomato juice, rich sources of vitamins A, B, C and D. He also claims that the oral administration of 25 grams of irradiated cholesterol, 1 gram of concentrated cod liver oil and 10 grams

of irradiated yeast daily is just as effective in the treatment of intestinal tuberculosis as is artificial heliotherapy. He adds, however, that irradiated cholesterol is apparently less effective than the others as it was fed to nine children with bone and joint tuberculosis for four months without any appreciable effect upon the healing process or increase in blood calcium or phosphorus. His report calls attention to the fact that apparently there is close relationship between the beneficial effects of heliotherapy and the increased formation of vitamin D as a result of the solar radiation.

The research work on the effect of diet in experimental tuberculosis seems to center about the use of calcium and the vitamins. Because calcium is so frequently found in healed lesions of tuberculosis, numerous attempts have been made to influence the rapidity of the healing process by increasing the blood calcium. That naturally raises the question as to whether there is a diminution in blood calcium in tuberculosis. According to Greisheimer and Van Winkle, tuberculosis is not characterized by a demineralization although the "C" group of cases showed lower calcium value than any of the other groups. Gordon and Cantarow claim that an increase in the normal calcium content of the blood has apparently no influence on the tuberculous process. McRae and Ingvaldson claim that "as vitamin D causes calcification in rickets, we may conclude that it should do likewise in tuberculosis." Grant, Bowen and Stegeman conclude that when calcium and vitamin D are decreased sufficiently there is a definite lowering of

the resistance to tuberculosis in rats and conversely that rats maintained on adequate diets could withstand many times the dose of tubercle bacilli which produced tuberculosis in rats maintained on a deficiency diet. Because of this they believed that the vitamin D content of the diet should be increased in gloomy weather to compensate for the lack of sunshine. An analysis of Grant's report in 1930 warrants one in concluding that she believes that when a diet is deficient the addition of vitamin D does not retard the tuberculous process but if the diet is already adequate a further addition of vitamin D seems to increase the resistance to tuberculosis, though a prolonged excess of vitamin D seems to lower it. She called attention to the fact that resistance to tuberculosis can be reduced by a prolonged disturbance in the optimal balance which should exist between calcium and vitamins C and D of the diet *without destroying the growth impulse*. McConkey and Smith claim that a diet partially deficient in vitamins A, C and D renders guinea pigs susceptible to intestinal tuberculosis. They believe that "a chronic partial deficiency of vitamin C is the most important factor in the production of clinical disease."

As the importance of vitamins in the diet is generally accepted the question of the value of commercial preparations of vitamins is raised. In this connection McCollum writes "The fact that we can readily prepare diets from ordinary foods which will contain several times the minimum amount of vitamins upon which present normal nutrition can be maintained over a considerable period of

time, tends to render academic the discussion about the advisability of taking concentrated commercial preparations of vitamins."

Hawes' report of the answers of thirty-six physicians to the following eight questions is very interesting as it indicates modern practice

1 Do you believe in lunches between meals? If so, under what conditions? Lunches between meals are rarely advisable. The average patient enjoys his food more and takes larger amounts of nourishment when he confines himself to three meals a day than in any other way

2 Do you advise egg-nogs? Egg-nogs in any form at any time are as Dr. Carroll Edson says, "An invention of the devil"

3 Do you believe in raw eggs? If so, how do you advise the patient to take them? Raw eggs are easily borne and if the patient is under weight, do not do any harm and may do good. They are not so digestible as cooked eggs and on the whole are rarely indicated

4. As a general proposition, how much extra milk is advisable? About one quart of milk a day, four or five glasses with meals, is the maximum amount that should be given. A glass of milk with each meal is usually sufficient

5 Do you lay down any definite laws about what special foods should be emphasized? There are no special foods that need be emphasized. Fruits and vegetables will help correct constipation. They contain vitamins but little if any nourishment. Potatoes, macaroni and rice contain much food value

6. Do you give any special directions about the care of the bowels? The bowels should act at least once daily. A mild laxative once a week is often a valuable help if a diet with plenty of roughage is not enough

7 Do you advise using large quantities of water? Five or six glasses of water with and between meals is advisable in every case

8 Do you emphasize rest before and after each meal? A rest before and especially after each meal is essential. The dictum approach and leave each meal in a rested condition is an especially good one to adhere to

Modern man has so developed his food supply that the poor man of today has a more varied and stable diet than did the wealthy man of a few centuries ago. For instance, due to the improvements in the canning industry we now have vegetables the year around. Therefore we no longer feel as run down in the spring as did our ancestors who took sulphur and molasses as a spring tonic

But even with his wonderful opportunities for a stable and well-balanced diet, modern man, particularly in Europe and America, is, in the opinion of McCollum, deriving too large a proportion of his food from cereals (35 to 45 per cent) supplemented by muscle meats, potatoes and sugar. He states that this combination of food does not support satisfactory development, longevity and fertility in any of the animals with which experimental studies have been conducted. Cereals which form the bulk of the diet are comparatively cheap but when used singly are deficient in proteins. When used in various combinations the pro-

tein deficiency of one individual cereal is supplemented by the protein content of another. Muscle meats are similar to cereals in that they are deficient in calcium and sodium chloride but they have become very palatable and modern man is using them freely to the exclusion of the rest of the carcass, thereby losing the protective foods which it contains. If man used more of the carcass as does the carnivorous animal, his diet would be better balanced and would not need to be supplemented by the protective foods. Carbohydrates, with the exception of honey which contains a small amount of vitamin B, are lacking in vitamins and their excessive use lowers the resistance of the body to infection in general.

Because of the deficiency of the above diet, it is necessary to supplement it by certain protective foods in order to improve nutrition and skeletal development and to increase the resistance of the body to infection in general. Milk, eggs, leafy vegetables and fruits belong to this group of foods. Milk is a very satisfactory article of food but it is inadequate when used as a sole source of nourishment over a long period of time. When used in combination with other foods it supplies their deficiency. Eggs are also very valuable for increasing the palatability of other foods, and are rich in vitamins A and D but poor in vitamin B. They are also deficient in calcium and favor putrefactive processes in the gastrointestinal tract but this tendency is counteracted when combined with carbohydrates and milk. Sea foods are very satisfactory sup-

plementary foods because the entire edible portion of the animal is used.

McCollum calls attention to the fact that there are two general types of deficiency diets, one which is marked and is followed by an acute reaction as beri beri or scurvy and a slight borderline deficiency which must be continued over a long period of time before its effect is felt. It is this latter type of deficiency diet which, because of its insidious nature, is so pernicious and harmful for man. There is much evidence to show that a good state of nutrition increases greatly the resistance of the body against certain types of infection while, on the other hand, an improper diet will cause inferior physical development, lack of recuperative powers and endurance and may result in accumulative fatigue with a lack of resistance to those infectious diseases where specific immunity is not usually developed.

That the skeletal development of man can be markedly influenced by diet is evidenced by the fact that the Japanese children born in this country and fed on an American diet will in the second and third generation be considerably larger than children of the same age who lived on a Japanese diet. Grant's conclusions also call attention to the fact that there is of necessity no specific relationship between the skeletal development or size and weight and resistance to tuberculosis. Russell reports as the result of his clinical observation on a number of dispensary cases, that while nutrition may have a marked effect upon the symptoms of tuberculosis it failed specifically to effect the course of the disease. That recalls a statement of Stewart

time, tends to render academic the discussion about the advisability of taking concentrated commercial preparations of vitamins "

It is this latter type of deficiency diet which, because of its insidious nature, is so pernicious and harmful for man. There is much evidence to show that a good state of nutrition increases greatly the resistance of the body against certain types of infection while, on the other hand, an improper diet will cause inferior physical development, lack of recuperative powers and endurance and may result in accumulative fatigue with a lack of resistance to those infectious diseases where specific immunity is not usually developed.

That the skeletal development of man can be markedly influenced by diet is evidenced by the fact that the Japanese children born in this country and fed on an American diet will in the second and third generation be considerably larger than children of the same age who lived on a Japanese diet. Giant's conclusions also call attention to the fact that there is of necessity no specific relationship between the skeletal development or size and weight and resistance to tuberculosis. Russell reports as the result of his clinical observation on a number of dispensary cases, that while nutrition may have a marked effect upon the symptoms of tuberculosis, it failed specifically to effect the course of the disease. That recalls a statement of Stewart

"that we put patients to bed because of symptoms and a lesion. We are prone to forget about the lesion and let them up when the symptoms have disappeared." Loss of weight is one of the symptoms of tuberculosis and we are all too apt today to forget about the lesion when the symptoms have disappeared and man's nutrition is back to normal or a little above and to conclude, as did the ancients that the individual is well.

CONCLUSIONS

There is much evidence to prove that there are certain minimum requirements as far as proteins, fats, carbohydrates, vitamins and minerals are concerned in order that normal health may be maintained. Metabolic studies in tuberculosis prove that increasing the diet beyond a certain point is detrimental to the cure of pulmonary tuberculosis because of the increased pulmonary activities necessitated by the increase in metabolism. As we believe that a diet which is well balanced and adequate for a man in health is sufficient as the basic diet for the person with tuberculosis, Glen Lake Sanatorium has prepared such a diet which, unless there is definite gastrointestinal pathology, or nutritional disturbances present, is essentially the same as would be provided for the non-tuberculous individual who is living under the same relative conditions of exercise. When however, such conditions are present, they should, of course receive just as prompt and careful treatment as they would, should they occur in a person without tuberculosis. The diet as planned provides

for about 3000 calories per day and includes half a pint of milk with each meal and at bed time, and contains 70 to 100 grams of protein and about 300 grams of carbohydrates. The balance is composed of fat. Those who are below weight receive an extra half pint of milk in the morning and afternoon. Of course, this is merely the basic diet and is modified as occasion demands. Out of a population of 640 adults we have at times served as high as a 125 special diets.

In planning this diet we have followed the general suggestions of McCollum as to the most satisfactory type of diet which represents "the best elements from those several systems of diets which have been thoroughly tested in human experience and have been found successful." In brief, these are, that if the protective foods such as dairy products, including one quart of milk daily and leafy vegetables, are used freely and also a certain amount of raw vegetables and fruits for their antiscorbutic properties (we use a fairly large amount of canned vegetables also which if one can judge from Byrd's two years' experience at the South Pole are also antiscorbutic) "the remainder of the food supply may safely be derived from any of our ordinary milled cereal products, tubers, root vegetables, sugar, and meats. Infants and children can be safeguarded in their skeletal development by providing at regular intervals a suitable amount of cod liver oil, and by affording an opportunity for outside exercise in sunlight."

BLOOD CHANGES IN BENZOL POISONING

In the nine years since Schultz described the condition now known as agranulocytic angina, it has become a disease of frequent occurrence. It is now evident that it is not an entity as was first believed, but rather a group of conditions, for in some cases there is granulocytopenia without angina, in others a severe aplastic anemia, and in still others a hemorrhagic diathesis dominates the clinical picture. Likewise there is a wide range of conditions with which granular leukopenia may be found associated: radium and X-ray irradiation, administration of arsenic compounds and especially asphenamine, benzol and its homologues and substitution products, and with pernicious anemia, aleukemic lymphoblastoma and lymphatic and myelogenous leukemia. With these there may or may not be sore mouth and angina. A necrotizing process against which the defensive powers of the body are powerless, or nearly so, may seem to have its origin in an operative wound, or to arise *de novo* on parts well away from the mouth. Does this group of morbid conditions constitute a new disease-concept or have we always had it with us? Is the apparent wave of leucopenic, aplastic anemic, and myelophthisic conditions, variously styled, the result of directed attention and therefore of better diagnosis? It so happens that certain of the known agencies capable of producing similar

effects upon the bone marrow and blood are those whose industrial and therapeutic use is rapidly increasing. What part of the increase may be thus explained no one can as yet determine.

The effect of benzol upon the blood and blood forming organs has been studied from the standpoint especially of the important industrial hazard which exists. Benzol (*benzene*, not *benzine*) is used for its solvent action, its fuel value, and as a starting point in the manufacture of various synthetic drugs, dyes and other products. It is employed in a variety of industries, including many branches of the manufacture of rubber, artificial leather and leather enamels, waterproof fabrics including rubber raincoats, window shades, lacquers, shellacs, paint removers, bronzing liquids and batteries, in dry cleaning, and in many other ways. For the past six years the annual production of benzol in this country has not fallen below 100,000,000 gallons.

In the present year two very important studies of benzol poisoning have appeared: a comprehensive review by Alice Hamilton* and an analysis of the literature with much original material added, by Carey P. McCord**

*ALICE HAMILTON, M.D., Benzene (benzol) poisoning, Arch. of Path., 1931, xi, 434-454, 601-637.

**CAREY P. MCCORD, M.D., Benzol (benzene) poisoning, a new investigation of the toxicity of benzene and benzene impurities, 1931, from The Industrial Health Conservancy Laboratories, Cincinnati, Ohio.

Their conclusions in regard to the blood are especially important. In the early stage of benzol action a leucopenia is not found, but on the contrary, the white cells are usually moderately increased. Continued exposure leads to a significant leucopenia, oftentimes as low as 500 cells per cubic millimeter if exposure is continued. Very rarely a leucocytosis persists. The establishment of an arbitrary level of depression of the white count as indicative of benzol poisoning has certain inherent dangers. The normal variation of an individual may swing over a range in which the maximum is 100 per cent greater than the minimum. Thus a fixed standard, such as that a decrease of 25 per cent from the normal white blood cell count constitutes a fair index of the presence of benzol poisoning, providing other conditions can be ruled out, must be applied with caution. Nevertheless, in the presence of this industrial hazard a sustained leucopenia of 25 per cent or more as based upon a knowledge of normal counts of the individual, is of diagnostic value, and any white blood cell count in the neighborhood of 5,000 or less in a benzol worker is fair evidence of poisoning if this degree of leucopenia persists in several counts distributed over one or more days. The red cells suffer a less severe reduction than the white cells. In the late stage of cases destined to be fatal red blood cell counts as low as 1,000,000 or even 500,000 have been found. Under the influence of benzol, basophilic red cells are present in numbers far higher than normal and occasional nucleated red cells are seen, but poikilocytosis, anisocytosis and hemolysis are by no means

constant, and in respect to these the literature is conflicting. The hemoglobin falls in proportion to the diminution in red blood cells, for the anemia is dependent upon injury to the bone marrow and not upon hemolysis. McCord was unable to find significant points of differentiation between the blood picture of benzol poisoning and that of the agranulocytosis of Schultz's angina. In all but the early stage of benzol poisoning the platelets are decreased and bleeding time is frequently prolonged. With platelet counts below 30,000, spontaneous hemorrhages are said to appear. Finally, and of great significance in duplicating the picture of agranulocytic angina, it has been shown by numerous workers that benzol may lower the infection-resisting powers of the body by diminishing antibodies. In fatal cases of chronic poisoning with benzol, infection nearly always plays a part and not infrequently necrotizing infectious lesions of the mouth are present. Thus in seeking extrinsic factors in the etiology of the leukopenic diseases benzol and its allies must be kept constantly in mind.

SAFETY FIRST

Seldom, indeed, has the physician been found deaf to a legitimate call for his services, a shirker when confronted with duty, or a coward. Neither has his apparent disregard for personal comfort and security been based upon ignorance of possible consequences to himself. At the present time it must be exceedingly rare for an emergency to arise in which a physician finds it necessary to aspirate a diphtheritic membrane from the

larynx of a dying child by mouth to mouth contact. It was not the discovery of the Klebs-Loeffler bacillus, however, which caused this act of heroism to become all but unknown at the present time. That the physician is responsive to duty without regard to himself is generally known, and the resulting situation has become part of the stock in trade of the outlaw. According to press reports, a Fellow* of the American College of Physicians received an emergency call over the telephone requesting him to go to a certain address, with the added appeal, "Please come quick, doctor, the baby is dying of pneumonia." Experiencing some difficulty in finding the number given, he was lured into a dark, and as afterwards appeared, vacant house by a man in the doorway who said, "Please hurry, doctor." Within the house he was struck repeatedly with a black jack, robbed of money and wrist watch and left dazed and apparently unconscious. After an interval he was able to recover his keys from the floor, reach his car, drive home, and summon aid. Such incidents have become increasingly more frequent. Robbery always has been the motive with sometimes assault added, as in the example recounted, or kidnapping. In the face of another year of economic stress, it cannot be hoped that the danger will be lessened. In some cities this situation has been met by arrangements with the police departments such that a physician answering night calls can, if he desires, have escort, or be met at the stated address by a police officer. This is easily man-

aged where radio-controlled scout cars are used for night patrol. The physician telephones his destination and time of arrival and his escort meets him at the address given or at a nearby street intersection. Through existing organizations physicians can properly request such aid in the performance of their recognized duty. Where similar plans are already in operation, physicians should not hesitate to avail themselves of the protection offered.

THE STANDARDIZATION OF AMERICAN SPECIALISTS

Several articles have appeared in the medical press of America during recent years concerning what might be termed the standardization of specialists. Under present conditions anybody who chooses to, provided he is qualified and registered, can set up office as a specialist in any of the many branches of medicine. He may or may not have any particular knowledge of the subject he professes to specialize in. I think, however, the great majority of men make it their business to take special instruction over a period of six to twelve months in the subject or subjects they wish to specialize in. The public as a whole expects great things of the specialist, and certainly takes it for granted that he possesses infinitely superior knowledge of his subject than his unfortunate much-maligned brother, the general practitioner, the public occasionally is quite wrong in this supposition. It would certainly appear that a more or less fixed standard is necessary, and as far as medicine is concerned I am of opinion that the American College of Physicians can be of tremendous

*M. K. Wylder, B.S., M.D., F.A.C.P., Albuquerque, N. M.

assistance in dealing with this problem. It should be a sort of "*sine qua non*" that no physician could be accepted as having joined the ranks of specialism proper unless he possessed at minimum the Associateship of the American College of Physicians. In some way or other the general public should be thoroughly instructed and made to understand this. It would be well if the Board of Regents and the Committee on Credentials at an early date very carefully considered the important and pressing question of holding an examination proper either written or clinical or both for admission to Associateship in the College; this might be held after the ordinary pre-

liminaries of investigation of the candidate's worth and suitability for nomination have been gone into in the usual way by the Executive Secretary and Committee on Credentials. This, to my mind, is the only practical way of facing the problem, and the examination of the American College of Physicians will have to be looked up to and known throughout the country as the hall-mark of specialization of the American continent, so far as medicine is concerned.

Der Abbau des Blutfarbstoffes im Verdauungstrakt des gesunden Menschen (The Breaking Down of Blood Pigment in the Digestive Tract of Healthy Men)
By FELIX HAUROWITZ (Arch f Verdauungs-Krankh, 1931, 1, 33-46)

After the ingestion of 50 cc of the subject's own blood, the feces were subjected to chemical analysis in order to determine the amounts of the various derivatives of blood pigment present. Control analyses were made for several days before ingesting the blood and the subject was maintained on a blood- and chlorophyll-free diet. By far the greater part of the blood pigment was recovered on the second and third days following ingestion as protohematin. Three groups of analyses showed an output of 85 to 90 per cent as protohematin, 5 to 8 per cent as deuterohematin, 2 to 3 per cent in the *protoporphyrin* fraction and $\frac{1}{2}$ to 1 per cent in the deuteroporphyrin fraction. The excretion of coproporphyrin was not significantly influenced by the ingestion of blood. Deuterohematin, and proto- and deuteroporphyrin are not derived from blood pigment through the agency of enzymes but through putrefaction. Native blood pigment (oxyhemoglobin and reduced hemoglobin) was not found in the stools. This is in agreement with the known rapid alteration of native blood pigment produced by gastric acidity. On the other hand alkaline trypsin solution alters blood pigment so slowly that native blood pigment may be demonstrated even after 24 hours. Thus the demonstration of occult native blood pigment (by its characteristic spectrum) in the feces comes to be of diagnostic significance in differentiating between bleeding into the acid stomach contents, or into an achyllic stomach or the alkaline upper small intestine, providing a source of blood from a lower level can be excluded. Methods for the analysis of feces for the qualitative and

quantitative recognition of the various blood pigment fractions are given in detail.

The Elimination of Phenolsulphonphthalein by the Kidney The Influence of Pathologic Changes in the Liver By J P HANNER, M D, and G H WHIPPLE, M D, Rochester, N Y (Arch Int Med, 1931, xlviii, 598-610)

For many years it has been known that an unusually high degree of renal elimination of phenolsulphonphthalein occurs in certain cases of toxemia or pregnancy. It was suspected that these cases were complicated by some abnormality of the liver. This question has been investigated by carefully controlled experiments in which liver injury has been produced in dogs by various means, and also by the determination of the mode of excretion in animals with complete obstruction of the common bile duct. It was found that the normal dog excretes from about 10 to 15 per cent of the usual dose of phenolsulphonphthalein by the hepatic route. When this pathway is blocked, the surplus appears in the urine, giving figures proportionately higher than would otherwise be found. Of that portion which escapes into the intestines in the normal animal, not more than 5 per cent is absorbed, so that reabsorption of the dye from the bile can be dismissed as a factor of no importance. In dogs with necrosis of the liver due to chloroform poisoning there is a distinct rise in the elimination of phenolsulphonphthalein by the normal kidney. With repair of the hepatic injury, the elimination of phthalein returns to normal. Phosphorus gives a similar but less striking reaction. After hepatic injury due to chloroform, the dog's liver does not remove phenolsulphonphthalein from the blood stream and does not excrete it in the bile. The portion which otherwise would have been removed by this route is therefore available

for excretion by the kidneys. Clinically, therefore, an unusually high renal elimination of phenolsulphonphthalein should suggest pathologic changes in the liver, and in the presence of combined renal and hepatic disease, great caution should be exercised in the estimation of the amount of renal injury.

A Study of the Blood Picture in Congenital Syphilis and the Effect of Antisyphilitic Therapy upon the Hemoglobin and Cellular Elements By H. HARRIS PERLMAN, M.D., and CARROLL S. WRIGHT, M.D. (Am Jr Syph, 1931, xv, 449-495)

Thirty-four patients with congenital syphilis were selected for this study. Diagnosis of syphilis was based upon history of the disease as existing in either parent, with clinical or roentgenographic manifestations and positive serologic reactions in the child. In age, these patients ranged between 2 and 14 years. Twenty-seven normal children within the same age range were used as a comparative normal control, and as a further control a group of 22 non-syphilitic, but under-nourished, children was established. It was found that the secondary anemia present in congenital syphilis does not differ from the anemias associated with various chronic infections, and that in both degree and kind, it may not differ from anemias which are discoverable in supposedly healthy children. No reliance could be placed upon the degree of anemia as a diagnostic sign, nor did the study of the individual cell types of the blood reveal anything of diagnostic or prognostic importance. Blood studies were carried out before and after various forms of antisyphilitic therapy. Arsenic or bismuth or a combination of these drugs was found to have a variable and inconsistent effect upon the secondary anemia and upon the differential count. In certain groups there was a greater loss than gain in hemoglobin, but in no single series was there any striking change referable to the treatment used.

A Study of Nephritis at the Canton Hospital By WILLIAM W. CADBURY, A.M., M.D., F.A.C.P. (Transactions of the Eighth Congress of the Far Eastern As-

sociation of Tropical Medicine, Bangkok, December, 1930. 19 pages.)

There is very little to be found in medical literature concerning nephritis among native Chinese. The general impression that Bright's disease is less prevalent in China than in Europe and America seems to be borne out by such statistics as could be collected, but the difference is not very great. In twenty-three institutions in China it was found that the percentage of nephritis to all hospital admissions varied from 0.25 to 1.00 in ten, from 1.02 to 1.69 in eleven, and in only two did the ratio exceed 2.00 per cent. In five large hospitals in the eastern part of the United States relative incidence of nephritis to all cases admitted varied from 1.33 to 3.18 per cent. The percentage of nephritis cases to medical admissions only was between 2 and 3 in four Chinese Hospitals, between 3 and 4 in five, 4.04 at Canton Hospital, 4.09 at Peiping Union Medical College, and over 6.00 at Hackett Hospital in Canton and the Government Civil Hospital in Hong-kong. In the five hospitals of the United States, with which comparison is made, the incidence of nephritis to medical admissions varied from 3.63 to 7.61 per cent. A larger proportion of nephritis cases was found in the hospitals of south and central China than in those of north China.

The Effect of Cortin in Asthenia By FRANK A. HARTMAN and GEORGE W. THORN (Proc Soc for Exp Biol and Med, 1931, xxix, 48-50)

The effect of cortin in the asthenia of a number of clinical conditions including Addison's disease has been investigated. Since increased susceptibility to fatigue is more significant in such conditions than the actual dynamic power of the muscle, a finger ergometer was used to test the threshold of fatigue. Four normal individuals showed a maximum increase in power to do work before the development of fatigue of from 50 to 500 per cent. The effect of cortin on the fatigue point was studied in six cases of Addison's disease, two in which the cortical insufficiency was almost absolute and four in which it was less marked. The threshold of fatigue was advanced 700 per

cent in one of the severe cases and none in the other. One of the less severe cases showed no increase, two increased 400 per cent and the fourth, 4900 per cent. Other conditions associated with asthma, in which improvement in susceptibility to fatigue, either symptomatic or ergometric or both, followed administration of cortin, were pregnancy, Graves' disease, muscular dystrophy, osteomyelitis, diphtheria and myasthenia gravis.

Cerebral Adiposity with Mental Deficiency and Retinitis Pigmentosa. The Lawrence-Biedl Syndrome. By EDWARD WEISS, M.D. (Endocrinology, 1931, xv, 435-441.)

Lawrence and Moon in 1866, Bardet in 1920, and Biedl in 1922, described a familial condition in which the affected individuals show retinitis pigmentosa, adiposity, genital hypoplasia, night-blindness, polydactylism and mental deficiency. This has since been called the Lawrence-Biedl syndrome and

the Bardet syndrome. The author adds the forty-eighth to the list of the reported examples of this syndrome. His patient was a girl, whose life age was fifteen years and eight months, and her mental age approximately five years. She was obese, weighing 194 pounds and had six toes on each foot. There was partial paralysis of the external rectus muscle of each eye, retinitis pigmentosa, and genital hypoplasia of moderate degree. It was formerly considered that this condition resulted from a disorder of the pituitary gland. More recently the tendency has been to regard a lesion of certain metabolic and genito-trophic centers in the floor of the midbrain as responsible. This is explained embryologically as dependent upon a genetic defect of the forebrain. Treatment with glandular extracts, chiefly thyroid and pituitary, has brought about improvement in some cases. This was true of the case reported.

Reviews

Human Heredity. By ERWIN BAUR, Professor of Heredity at the Agricultural Academy in Berlin, EUGEN FISCHER, Professor of Anatomy and Director of the Anatomical Institute at the University of Freiburg, Breisgau, and FRITZ LENZ, Professor of Racial Hygiene at the University of Munich. Translated by EDEN and CEDAR PAUL. 734 pages, 172 illustrations, and 9 plates. The Macmillan Company, New York City, 1931. Price, \$8.00.

This book is an English translation of the third edition of *Menschliche Erblichkeitslehre*, which was published in Munich in 1927, with supplementary material supplied during the preparation of the English version. The text is divided into five sections. The first section, by Baur, reviews briefly and clearly the general theories of variation and heredity. The second part, contributed by Fischer, treats of racial differences in mankind. From a consideration of the characters responsible for the differ-

ences in the external appearances of individuals the author proceeds to a discussion of racial origins and racial biology, and a description of the races of mankind. In classifying the so-called normal types of man, the author follows the usual German method of division into asthenic, pyknic, and athletic groups. Yet a considerable proportion of "normal" individuals fail to conform to any one of these three classes, so that this classification is far from satisfactory. The final three sections are all by Lenz and deal with morbid hereditary factors, with methodology in human heredity and with the inheritance of intellectual gifts, respectively. Many will find it impossible to subscribe to the definition of disease as "the state of an organism which is on the borderline of its capacity for adaptation," when such a conception causes the author to designate color blindness as an anomaly not coming within the category of disease. Practically all disease conditions

in which the hereditary factor is important in etiology are considered in this section and genealogical diagrams are presented for many of them. The importance of heredity in the etiology of neoplasms is recognized and discussed and here the genealogical tree of the remarkable cancer family described by Warthin is reproduced. Rather more weight is given to the factor of hereditary predisposition in the causation of rickets than is generally accepted. Distinction is made between *blastophthoria* and *idioknesis* in that the latter term is limited to hereditary alterations in the germ plasm induced by extrinsic agents. The work of translation has been unusually well done. The style is clear and free from the original idiom. This book should be read by all who are concerned with the medical and genetic aspects of the inheritance of disease.

Diagnostic Methods and Interpretations in Internal Medicine. By SAMUEL A. LOEWENBERG, M.D., F.A.C.P., Associate Professor of Medicine, Jefferson Medical College, Assistant Physician to the Jefferson Hospital, Visiting Physician to the Philadelphia General Hospital, the Northern Liberties Hospital and the Eagleville Sanatorium for Consumptives, formerly Assistant Professor of Physical Diagnosis at the Medico-Chirurgical College and the University of Pennsylvania, Philadelphia. Second Revised Edition. xxiii + 1032 pages. 547 illustrations, some in colors. F. A. Davis Company, Philadelphia, 1931. Price \$10.00 net.

This second edition of Loewenberg's *Diagnostic Methods* contains new material on the cardiac blood supply and innervation, massive pulmonary collapse, coronary thrombosis, hypertension and hypotension, sickle cell anemia, von Jaksch's anemia, agranulocytic angina, acute mononucleosis and the diagnostic importance of certain findings in the cerebro-spinal fluid. In order to incorporate some of this it has been necessary to interpolate a few new pages which are lettered in order to avoid complete re-paging. The well chosen illustrations and diagrams continue to be one of the valuable features of this work. The half-tones are not always satisfactorily reproduced but the

difficulty lies in the always present dilemma in choosing between a stock which will do justice to the cuts and one which will keep the volume within reasonable limits of size and weight. Many of the illustrations of gross pathology are of terminal stages or unusually severe manifestations. Perhaps they tell their story all the more emphatically because of this, but they should not be considered type forms. The reviewer is of the opinion that this book will gain in usefulness if, in the next edition, the space which is now devoted to very brief presentations of certain external and largely surgical conditions is utilized for a more complete exposition of the diagnosis of diseases of the internal organs. To illustrate this point, carcinoma of the breast is given seven lines of text and one and one-half pages of illustrations. Not much can be done with the diagnosis of carcinoma of the breast in seven lines, but in that brief paragraph the curious statement, presumably a typographical error, occurs that '*the lymphatic gland becomes enlarged*'. On the opposite page, polythelia, or polythelism, is designated *polythelm*, a form for which the reviewer fails to find authority. Since the diagnosis of carcinoma of the breast could not be presented adequately, it would have been more useful to have devoted this space to fuller treatment of some condition which presents a constant problem to the internist, as, for instance, bronchogenic carcinoma. In the brief discussion of this far from rare condition, no distinction is made, save in the section on radiography, between sarcoma and carcinoma, primary and secondary, in the lung. The general sections of the book rise to a high level of excellence. The difficult chapter on the examination of the respiratory system is especially well done, the many line drawings adding much to the clarity of the exposition and providing the necessary mechanistic explanation for many physical signs. In many respects this is an excellent textbook.

The Infant Welfare Movement in the Eighteenth Century. By ERNEST CAULFIELD, M.S., M.D., with a foreword by GEORGE FREDERIC STILL, M.A., M.D. (Cantab.), Hon. LL.D. (Edin.), F.R.C.P.

(London) xv + 203 pages 8 illustrations Paul B Hoeber, Inc, New York City, 1931 Price, \$2.00

"To all who are concerned in the welfare of children and in the steps by which the present almost over-anxious care of childhood has been reached, this book by Dr Ernest Caulfield will be of absorbing interest" Thus wrote G F Still in the Foreword Since in this day and age practically everyone is interested in the welfare of children, the appeal should be practically universal and the reviewer feels that such will prove to be the case The period dealt with is one in which there was an awakening of an individual and social consciousness of the value of child life Of the two decades, 1730-1750, it was stated that 75 per cent of all of the children christened in London were dead before they reached the age of five Children had been regarded as a necessary evil, and evidence of neglect, cruelty, and infanticide is readily attainable from contemporary sources Within the eighteenth century, however, there was seen at least the beginning of a different attitude toward the child Thomas Coram, William Cadogan, Jonas Hanway and George Armstrong are those about whom the story of this movement centers Although historical, this work never becomes a catalog of men or events, and it is enlivened by numerous direct quotations from original sources To a large circle, both within and without the profession of medicine, this book is heartily recommended

Diabetes Its Treatment by Insulin and Diet A Handbook for the Patient By ORLANDO H PERRY, A M, M D, F A C P, Professor of Diseases of Metabolism, Graduate School of Medicine, University of Pennsylvania, Physician in Charge of Departments of Diseases of Metabolism, Hospitals of the Graduate School of Medicine, University of Pennsylvania, and Philadelphia General Hospital, Consultant in Diseases of Nutrition and Metabolism, Shriners' Hospital for Crippled Children, Philadelphia Unit Fifth revised and enlarged edition 231 pages, illustrations and tables F A Davis Company, Philadelphia, 1931

The fifth edition of this handbook has been extensively revised The section on vitamins has been rewritten and enlarged, the subject of obesity and diabetic hygiene has been discussed in greater detail, and twenty-one pages of sample diets for those following the orthodox dietary rules of the Jewish faith have been added As is stated in the preface this is a book for the diabetic and not for the physician, but it is not intended to be a substitute for the physician The latter will find it an aid in giving the patient such a practical working knowledge of diabetes that his intelligent cooperation will be had It can be recommended safely for this purpose, but the physician should first become thoroughly familiar with its contents in order that no apparent differences in methods or explanations may appear

Pediatric Education Report of the Subcommittee on Medical Education, Section on Medical Service, White House Conference on Child Health and Protection 109 pages The Century Company, New York and London, 1931

The adequacy of the medical school teaching of pediatrics as judged by the opinion of the practicing physician, the proper position of pediatrics in the organization of medical schools, the minimum teaching facilities for pediatrics, and salient points to be presented in both undergraduate and graduate teaching are the subjects considered in this report The basic information used was obtained largely by the questionnaire method and consequently labors under certain limitations Nevertheless, teachers of pediatrics and medical school executives will find much that is thought-provoking and helpful in the data presented

On Phasic Introductory and Release Effects of the Cocaine Group on Vessel Preparations and an Attempt at a General Appraisal of Phase Effects By EDWARD RENTZ, Pharmacological Institute, Riga Translated and abstracted by LINN J BOYD, M D, F A C P, Professor of Pharmacology, New York Homeopathic Med-

ical College and Flower Hospital 146 pages Privately printed, 1931

Frog blood-vessel preparations were used in obtaining the basic data in a comparative study of the effects of cocaine and of a series of related substitution products as used in varying dilutions The resulting phasic effects are discussed in detail and their theoretical aspects considered in the light of what is known about similar reversible and cyclic modes of behavior induced by other substances Those interested in this field of investigation will find here a very large material and a reference list comprising 656 items

Permeabilitätsstudien an der Darmschleimhaut [Permeability of the Intestinal Mucosa] Von DOZENT DR HANS PATRATH, Assistant der Kinderklinik der Medizinischen Akademie in Dusseldorf 115 pages S Karger, Karlstrasse 39, Berlin, 1931. Price, Rm 8

This monograph is an experimental and clinical study of the permeability of the mucosa of the small intestine with special regard to the etiology of intestinal intoxication of infancy Apparatus and methods of investigation are described and the results obtained from several groups of substances under varying conditions are analyzed and presented

American Gastro-Enterological Association Transactions, 1930 xiii + 169 pages, numerous illustrations Paul B Hoeber, Inc, New York City, 1931 Price \$3.00

In this volume are gathered 27 scientific papers from the thirty-third annual meeting of the American Gastro-Enterological Association held at Atlantic City, New Jersey, May 5 and 6, 1930 Review of each of these is impossible The eminence of the authors in their respective fields and the selection of the topics as those most significant in present day gastro-enterology are a sufficient earnest of the worth of this collection of reports of original investigations

Anesthésia geral pelo Protótydo de Azoto [Surgical anesthesia with nitrous oxide]

By Dr PEDRO AYRES NETTO Doctoral thesis from the Faculdade de Medicina de São Paulo 287 pages, 33 ills Empresa Graphica de "Revista dos Tribunaes", São Paulo, Brazil, 1931

This thesis contains a detailed study of nitrous oxide as a surgical anesthetic, with survey of the literature and data derived from animal experimentation and personal observations of its clinical use A bibliography of 250 items is added

The Psychology of Insanity By BERNARD HART, MD (Lond.), F R C P (Lond.); Fellow of University College, London, Physician in Psychological Medicine, University College Hospital and National Hospital, Queen Square, London Fourth edition xi + 191 pages The Macmillan Company, New York City, 1931 Price, \$1.25

This book was first brought out in 1912 and to the present edition, the fourth, but little new material has been added The relationship of the simple fundamental principles, as previously stated, to the structure of modern psychopathology has been made more evident by a new introductory chapter 19 pages in length and by occasional explanatory footnotes This book makes no pretense of being a complete treatise at any point Rather it is an *Einführung* leading the beginner by a logical approach and with proper emphasis upon historical development to the point from which the many independent schools of thought of the present day diverge For this reason those who seek a full exposition of the theories of Freud will not find them, for so far as Freudism is concerned this book aims to bring only certain selected aspects of Freud's teachings into relation with the lines of advance followed by other investigators, and thus to demonstrate that the conceptions of psychopathology have been built up in accordance with the rules and principles governing the development of other sciences To the medical student, physician, or to the general reader who desires background material or an introduction to the more obviously technical and partisan treatise, this small book can be fully recommended

College News Notes

REDUCTION IN REPRINT PRICE LIST

Attention of contributors to the ANNALS OF INTERNAL MEDICINE is called to the new price list of reprints appearing on the outside back cover of this journal, beginning with the November, 1931, issue. In quantities of four hundred or more a saving of from twelve and one-half per cent to thirty per cent has been effected and passed on to authors in reduced rates.

This saving is wholly due to a change in the paper stock used in ANNALS and in the reprints. Formerly two grades of paper, "antique" for ordinary purposes and enameled stock for illustrations, were used. The mixing of two grades of paper was not only expensive, but detracted from the appearance of the journal. For the November and subsequent issues, through the co-operation of the printers, "Andover plate" is used, making the stock uniform throughout the journal, and adding materially to its appearance.

Dr. James D. Bruce (Fellow and Governor for Michigan), Ann Arbor, Michigan, has been appointed by the Regents of the University of Michigan to the position of Vice President of the University in Charge of University Relations. In this new capacity Dr. Bruce will supervise all of the University's extramural activities. His title at the time of his appointment to a vice presidency was Director of the Department of Post-Graduate Medicine, Member of the Executive Committee of the Medical School and Medical Adviser to the University Health Service.

Dr. Edward S. Calderwood, Dr. Frederick T. Lord and Dr. Joseph H. Pratt (Fellows), Boston, are members of a special Advisory Committee organized for the "purpose of studying the epidemiology, of promoting

prompt diagnoses, of encouraging and facilitating earlier and more general therapeutic use of concentrated serum, of improving methods for serum productions, of correlating the studies on serum production with the results following its clinical use, and of devising procedures for the future prevention, serum treatment and control of pneumonia."

The Commonwealth Fund of New York has made an annual appropriation of \$36,200 for three years to the Massachusetts Department of Health for this study. Various hospitals in different parts of the State will be selected to conduct a special service for pneumonia. Several laboratories will be chosen as pneumococcus type determination stations, and their technicians trained at the expense of the Fund. The Bacteriologic Laboratory of the State Department of Health will continue to make type determinations.

At the Second Annual Fall Clinical Conference of the Oklahoma Medical Society, held at Oklahoma City, November 2-5, many members of the College contributed as shown by the following report. Dr. James B. Herrick (Fellow), Chicago, and Dr. Leroy S. Peters (Fellow), Albuquerque, were among the distinguished guest speakers. Dr. Herrick delivered an address on "Embolism as Seen by the Internist." Dr. Peters delivered two lectures, one on "Treatment of Tuberculous Cavities," and one on "The Interpretation and Discussion of X-Ray Negatives of the Chest."

Other Fellows who gave addresses are indicated below. Unless otherwise mentioned, they reside in Oklahoma City.

Dr. Arthur White—"Digestive Disorders Due to Lesions of the Stomach,"

Dr. Lea A. Riely—"Digestive Disorders Due to Lesions of Biliary Tract,"

Dr C J Fishman—"Intestinal Indigestion,"

Dr H W Butler—"Anomalies of Heart,"

Dr Ray M Balyeat—"Asthma,"

Dr Leila Andrews—"Functional Heart Disorders,"

Dr Wann Langston—"Management of Non-Valvular Myocardial Failure,"

Dr L J Moorman—"Modern Methods of Treatment of Advanced Pulmonary Tuberculosis,"

Dr John Heatley—"X-Rays of Lower Spine,"

Dr E S Lain—"Lesions of the Mouth and their Etiology,"

Dr. Tom Lowry—"Purpura "

Dr John F Kenney (Fellow), Pawtucket, R I, addressed the Rhode Island Medical Society at their last meeting, on "Recent Studies in Etiology of Appendicitis "

At the opening meeting of the Memorial Hospital Staff, Pawtucket, Dr Kenney read a paper on "Gastric Hemorrhage from other Causes than Ulcer "

Dr. Samuel M Feinberg (Fellow), Chicago, Ill, addressed the Will-Grundy Medical Society at Joliet, November 4, on "Allergy in Every-Day Practice "

At a meeting of the Royal Academy of Belgium held on June 27, Dr George R Minot (Fellow), Boston, Mass, was elected "Correspondent étranger de l'Académie royale de Médecine de Belgique "

Dr Soma Weiss (Fellow), Boston, Mass, addressed the New York Academy of Medicine at its Fourth Annual Graduate Fortnight, Beth Israel Hospital, New York, October 21, on "Paroxysmal Cardiac Dyspnea "

Dr William B Castle (Fellow), Boston Mass, Assistant Professor of Medicine at Harvard University Medical School and Associate Physician to the Thorndike Memorial Laboratory of the Boston City Hospital, is on leave of absence in Porto Rico where he is undertaking extensive studies

concerning anemia, sprue, uncinariasis and other conditions, and studying further the alteration of gastric function in anemia.

Dr Kelso A Carroll (Fellow), formerly of Tucson, Ariz, has accepted the position of Medical Officer in Charge of the Soldiers' Tubercular Sanatorium at Sulphur, Oklahoma

On the evening of October 6, Dr Robert M Moore (Fellow), Indianapolis, Ind, addressed the Vanderburgh County Medical Society at Evansville, on "Some Considerations of the Heart in Surgery "

The following Fellows of the College delivered papers before the Academy of Medicine, Parkersburg, W Va, November 5, as indicated

Dr Henry K Mohler, Philadelphia—"Auricular Fibrillation, An Analysis of 220 Cases,"

Dr Louis H Clerf, Philadelphia—"Bronchoscopy in the Diagnosis and Treatment of Pulmonary Disease "

At the annual meeting of the Montana State Medical Society, held at Bozeman this summer, Dr Harold W Gregg (Fellow), Butte, Mont, read a paper entitled "Notes on Early Montana Medical History "

Dr John Huston (Fellow), Milwaukee, Wis, was recently appointed Medical Editor of the Wisconsin Medical Journal

At the last regular meeting of the Denver Sanatorium Association Dr I D Bronfin (Fellow), Denver, was elected President for the coming year

Dr Frank Parsons Norbury (Fellow), Jacksonville, Ill, Consultant in Neuropsychiatry, Wabash Railway Hospital Service, delivered a paper entitled "The Importance of the Psychoses as Contributing to Disabilities Among Railway Employees" at the 49th annual meeting of the Wabash Railway Surgical Society at St Louis, Mo, November 2

Dr Oscar W Bethca (Fellow), Professor of Therapeutics in the Graduate School of Medicine of the Tulane University of Louisiana, delivered an address at Oxford, Miss, October 29, on "Recent Developments of Diagnosis in Chest Diseases"

A medical clinic on Pernicious Anemia recently held by Dr E Roland Snader, Jr (Fellow), Clinical Professor of Medicine at the Hahnemann Medical College of Philadelphia, was published in the October number of the Hahnemannian Monthly

Dr Frederic J Farnell (Fellow), Providence, R I, was elected a member of the Board of Directors of the American Prison Association, October 21, at Baltimore, Md

Dr E J G Beardsley (Governor and Fellow), Philadelphia, Clinical Professor of Medicine at the Jefferson Medical College, held a clinic at the Mercy Hospital, Altoona, Pa, October 27, which was attended by 150 physicians from Blair and adjoining counties

Dr Samuel A Levine (Fellow), Boston, Mass, addressed the New Haven Medical Society, October 7, on "The Clinical Significance of a Systolic Murmur"

Dr J W Torbett (Fellow), Marlin, Texas, was elected Vice-President of the Texas State Medical Association at the last meeting, and was made Chairman of the Committee for Cancer Control to carry on the educational work with the laity and medical profession this year

During the recent Ninth Annual Clinical Conference of the Kansas City Southwest Clinical Society, held in Kansas City, Mo, Dr Robert A Cooke (Fellow), New York City, spoke on "The Clinical Manifestation of Allergy," and conducted a clinic on "The Diagnosis and Management of Asthma" Dr A Morris Ginsberg (Fellow), Director of Clinics, conducted a class on "The Differential Diagnosis of Incipient Tuberculosis, Early Thyrotoxicosis and Effort Syndrome"

The following Fellows of the College conducted classes

Dr P T Bohan, Kansas City, Mo—Heart Therapy,

Dr Harry Jones, Kansas City, Mo—Miscellaneous Heart Disease,

Dr D D Stofer, Kansas City, Mo—Non-Infectious Heart Disease,

Dr Sam Snider, Kansas City, Mo—Pulmonary Tuberculosis—Recent Advances,

Dr J V Bell, Kansas City, Mo—Pneumothorax in Tuberculosis,

Dr W W Duke, Kansas City, Mo—Allergy in General Medicine,

Dr A C Clasen Kansas City, Mo—Nutritional and Deficiency Diseases

Dr Lindsay S Milne (Fellow), Kansas City, Mo, conducted a clinic on "Valvular Heart Disease," and Dr A Comingo Griffith (Governor and Fellow), Kansas City, Mo, gave a clinic on "Rare Medical Cases" Also, Dr W A Myers (Fellow), Kansas City, Mo, conducted a clinic on "Bladder Disturbances Associated with Lumbosacral Lesions"

Dr Louis H Clerf (Fellow), Philadelphia, read a paper before the Tri-City Pediatric Society, October 17, held at Philadelphia, entitled "Bronchiectasis in Children Bronchoscopic Observations"

Doctors Salvatore Lojacono (Fellow), Marquette, Mich, Superintendent of the Morgan Heights Sanatorium, and Frank H Bartlett, Jr (Fellow), Muskegon, Mich, Medical Director of the Muskegon County Tuberculosis Sanatorium, were elected trustees of the Michigan Tuberculosis Association at the annual meeting of the organization on October 16

Dr Lojacono was recently re-elected Secretary-Treasurer of the Michigan Sanatorium Association

Dr George L Lambright (Fellow) Cleveland, Ohio, gave an illustrated address before the Cleveland Academy of Medicine, October 16, on "Diverticulitis"

Dr Egerton Crispin (Fellow and Governor), Los Angeles, Calif, was elected

President of the Association of Resident and Ex-Resident Physicians of the Mayo Clinic and Mayo Foundation at the annual meeting held in Rochester, Minnesota, October 8-10

Dr Karl Rothschild (Associate), New Brunswick, N J, attended the International Neurological Congress at Berne, Switzerland, during the past summer. He read a paper entitled "Concussion of the Pons"

Dr Rothschild was elected a member of the American Psychiatric Association at its recent meeting held in Toronto

The following Fellows of the College are authors of articles appearing in the September, 1931, issue of the Journal of Laboratory and Clinical Medicine

Dr John R Williams (Fellow), Rochester, N Y—"Case Report of Extensive Atrophy of Subcutaneous Fat Following the Repeated Injections of Insulin" (abstracted in the November ANNALS),

Dr Miles J Breuer (Fellow), Lincoln, Nebr—"A Method for Urinary Urea"

The Interstate Postgraduate Medical Association of North America held its annual meeting at Milwaukee, Wis, October 19-23, under the presidency of Dr Henry A Christian (Fellow), Boston, Mass

The following Fellows of the College presented clinics as indicated

Dr Elsworth S Smith, St Louis, Mo
—Diagnostic Clinic (Medical),

Dr Harlow Brooks, New York, N Y
—Diagnostic Clinic (Medical),

Dr Henry A Christian Boston, Mass
—Diagnostic Clinic (Medical),

Dr W. McKim Marriott, St Louis, Mo—Diagnostic Clinic (Pediatric),

Dr James H. Means, Boston, Mass
—Diagnostic Clinic (Medical),

Dr John H Musser, New Orleans, La
—Diagnostic Clinic (Medical),

Dr Cyrus C Sturgis, Ann Arbor, Mich—Diagnostic Clinic (Medical),

Dr. Elliott P Joslin, Boston, Mass—
Diagnostic Clinic (Medical),

Dr Leonard G Rowntree, Rochester, Minn—Diagnostic Clinic (Medical)

The following Fellows of the College offered papers as indicated

Dr S F. Haines, Rochester, Minn—
"The Use of Iodine in Recurrent Exophthalmic Goiter,"

Dr. Elsworth S. Smith St Louis, Mo
—"Cardiac Irregularities Associated with Diseases of the Thyroid Gland,"

Dr S Marx White, Minneapolis, Minn
—"Mechanism and Transmission of Heart Murmurs with a Special Consideration of 'The Unimportant Murmur,'"

Dr. William S Middleton, Madison, Wis—"Syphilitic Aortitis,"

Dr William S McCann, Rochester, N Y—"Syndrome of Ayerza,"

Dr Charles A Elliott, Chicago, Ill—
"Circulatory Failure in Acute Infectious Diseases,"

Dr Louis Hamman, Baltimore, Md—
"Prognosis of Hypertension,"

Dr Harlow Brooks, New York, N Y
—"Coronary Thrombosis,"

Dr Henry A Christian, Boston, Mass
—"Aortic Lesions in Relation to Cardiac Physical Signs and Cardiac Function,"

Dr Warren T. Vaughan, Richmond, Va—"Allergic Diseases,"

Dr William Gerry Morgan, Washington, D C—"Does Peptic Ulcer Cause Permanent Disability?,"

Dr W. McKim Marriott, St Louis, Mo—"Infantile Paralysis,"

Dr James S McLester Birmingham, Ala—"Recent Advances in the Treatment of Nephritis,"

Dr Leonard G Rowntree, Rochester, Minn—"Water in Relation to Health and Disease,"

Dr William A White, Washington, D C—"Suggestions from Medical Psychology in the Field of General Medicine,"

Dr B R Kirklin, Rochester, Minn—
"Roentgenological Diagnosis of Early Tuberculosis,"

Dr Willis F Manges, Philadelphia, Pa—"Bronchial Obstruction, Partial

or Complete as shown by the Roentgen Ray Examination,"

Dr Paul A O'Leary, Rochester Minn—"Therapeutic Problems of Syphilis,"

Dr James H Means, Boston, Mass—"Significance of Hyper- and Hypometabolism,"

Dr Hugh S Cumming Washington, D C—Address,

Dr James E Paullin, Jr, Atlanta, Ga—"Different Forms of Jaundice and their Significance,"

Dr John H Musser, New Orleans, La—"The Medical Treatment of Gall Stones and Cholecystitis,"

Dr Cyrus C Sturgis, Ann Arbor, Mich—"Present Aspects of Treatment of Pernicious Anemia,"

Dr Elliott P Joslin, Boston, Mass—"Complications and Sequelae of Diabetes"

Dr Austin B Jones (Fellow), Kansas City, Mo, was recently elected President of the Internist Club, an organization of internists in Greater Kansas City

Dr Albert F Tyler (Fellow) Omaha, Nebr, is the author of an article entitled, "The Treatment of Epitheliomas by Physical Methods," which appeared in the November, 1931, issue of the Nebraska State Medical Journal

The following Fellows of the College are members of a Committee on Heart Disease, which was recently formed by the Arkansas Medical Society

Dr Arthur G Sullivan, Hot Springs,

Dr Arless A Blair, Fort Smith

The purpose of the Committee is "to acquaint the physicians of the State with recent advances in the diagnosis and treatment of heart disease by publishing articles in the state journal, presenting papers, and sponsoring scientific exhibits at the annual meetings"

At the recent annual meeting of the Kentucky State Medical Association, Dr Philip F Barbour (Fellow), Louisville, was elected President, and Dr C N Kavanaugh

(Fellow), Lexington, was elected Orator in Medicine

Dr Edwin C Ernst (Fellow), St Louis, Mo, acted as chairman of the Local Committee on Arrangements of the Radiological Society of North America, which held its seventeenth annual meeting in St Louis, November 30 to December 4

Dr Ray M Balyeat (Fellow), Oklahoma City, gave an illustrated address on "Etiology of Allergic Diseases" before the Tri-County Medical Society, October 1

Dr William Bernard Yegge (Fellow), Denver, addressed the Boulder County Medical Society, October 8, on "Diagnosis and Treatment of Gastric Ulcer"

During the months of October, November and December, under the auspices of the American Association of Social Workers and the American Association of Hospital Workers, a series of medical lectures for social workers was given at the Medical and Chirurgical Faculty Building, Baltimore, Md. The following Fellows of the College spoke on the dates indicated

Dr Henry M Thomas, Jr, October 19 and 23—"Bright's Disease, Diabetes, Pneumonia" and "Glands of Internal Secretion," Dr Thomas also spoke on December 21, on "Diseases of Old Age—Convalescence",

Dr Lewellys F Barker, November 2—"Nervous Diseases—Locomotor Ataxia, Paralysis Agitans, Psychoneurotic States",

Dr Victor F Cullen, November 10—"Tuberculosis,"

Dr Louis P Hamburger, December 15—"Minor Ailments—Aspects of Heart Disease"

The Hennepin County (Minn) Medical Society was addressed on October 5 by Dr Moses Barron (Fellow), Minneapolis, on "Purposes and Function of a Medical Society" Dr Barron also delivered an address before the Minnesota Academy of Medicine at Minneapolis, on "Importance

of Hepatomegaly and Splenomegaly in Differential Diagnosis"

At the annual meeting of the Medical Society of Pennsylvania October 5-8 at Scranton, Pa., the following officers were elected

Dr William H Mayer (Fellow), Pittsburgh, President,

Dr Charles Falkowsky, Jr (Fellow), Scranton, President-Elect,

Dr Walter F Donaldson (Fellow), Pittsburgh, Secretary

Dr Anton J Carlson (Fellow), Professor of Physiology at the University of Chicago, delivered the third annual William T. Bel-field Lecture of the Chicago Urological Society on October 29, in the auditorium of the Medical and Dental Arts Bldg. Dr Carlson's subject was "Rejuvenation"

Dr Andrew B Rivers (Fellow), Rochester, Minn. addressed the 46th semiannual meeting of the Eleventh Indiana Councilor District Medical Association, October 15, on "Cause of Hematemesis"

Dr Harry Gauss (Fellow), Denver, Colo., spoke on "Nervous Indigestion" at the sixty-first annual meeting of the Colorado State Medical Society, September 16. On October 27, he was a guest speaker at the forty-fifth annual meeting of the Colorado Homeopathic Society, where he delivered an address on "The Basis of Diet"

Dr Gauss also was a guest speaker at the seventh annual meeting of the Colorado Hospital Association held jointly with the Colorado Dietetics Association, where he spoke on "The History of Diet in Fever"

Doctors Willis F Manges (Fellow), Philadelphia, E J G Beardsley (Governor and Fellow), Philadelphia, and H L Tonkin (Associate), Williamsport, addressed the Lycoming County (Pa.) Medical Society at the Annual Clinic of the society at the Williamsport Hospital on November 13

Dr George A Harrop Jr (Fellow), Baltimore, addressed the Baltimore City Medical Society October 23 on "Treatment

of Addison's Disease with Adrenal Cortical Hormone"

Dr Howard R Hartman (Fellow), Rochester, Minn., recently delivered one of the second annual series of graduate lectures offered to physicians of Northampton, Pa., and surrounding counties under the auspices of the Easton Hospital. Dr Hartman's subject was "Gastric Lesions and Gastric Hemorrhage"

Dr William H Mayer (Fellow), Pittsburgh, delivered an address, October 15, on "Fundamentals of the Mental Hygiene Problem" before the Cambria County Medical Society at Johnstown, Pa.

Dr Horton R Casparis (Fellow), Nashville, Tenn., discussed "Sinus Conditions in Childhood" before the Chattanooga and Hamilton County (Tenn.) Medical Association, October 8

Lieut Comdr Franklin F Murdoch (Fellow) has been appointed Professor of Tropical Medicine at the George Washington University School of Medicine

Dr James H Hutton (Associate), Chicago, addressed the La Salle County (Ill.) Medical Society, October 27, on "Recent Advances in Endocrinology"

Dr Bavard T Horton (Fellow), Rochester, Minn., spoke on "Buerger's Disease," before the Stephenson County (Ill.) Medical Society on October 15

Dr Oscar W Bethea (Fellow), New Orleans, La., recently addressed the Iberville Parish Medical Society on "Recent Advances in Diagnosis"

"Histamine in the Study of Gastric Secretion and Disorders of the Stomach" was the title of an address delivered before the Kalamazoo Academy of Medicine, October 20, by Dr Charles I Brown (Fellow), Ann Arbor, Mich.

Dr George I Lambright (Fellow), Cleveland, addressed the Cleveland Academy

of Medicine, October 16, on "The Problem of Arthritis"

Dr Frank Smithies (Master), Chicago, Ill., addressed the Mahoning County (Ohio) Medical Society at Youngstown, October 27, on "Gastrorrhagia—Its Pathological and Clinical Significance and its Management"

Dr Frederick G Banting (Fellow), Professor of Medical Research at the University of Toronto Faculty of Medicine was the recipient of the honorary degree of Doctor of Science at the annual convocation of the University of the State of New York at Albany, October 15

The eighty-fifth semiannual meeting of the Southern California Medical Association was held at Hollywood, Calif., November 13-14, under the presidency of Dr Fred B Clarke (Fellow), Long Beach. The following Fellows of the College delivered papers as indicated below

Dr Samuel Ayres, Jr, Los Angeles—
"Use of the Patch Test in the Diagnosis of Contact Dermatitis,"

Dr Raymond G Taylor, Los Angeles—
"Some of the Causes of Failure in Treatment of Cancer"

Dr J Curtis Lyter (Fellow), St Louis, addressed the Randolph County (Ill.) Medical Society, October 20, on diagnosis and treatment of diseases of the heart

On October 28, Dr James B Herrick (Fellow), Chicago, addressed the Medical History Club of the University of Illinois College of Medicine. Dr Herrick's subject was "Auenbrugger and Laennec"

Dr Harold W Palmer (Associate), Wichita, Kansas, spoke on "Hypothyroid States" before the October 20 meeting of the Sedgwick County (Kansas), Medical Society

Dr Sidney A Slater (Fellow), Worthington, Minn., was recently elected President of the Southwestern Minnesota Medical Association

Dr Thomas Grier Miller (Fellow), Philadelphia, addressed the Atlantic County Medical Society at Atlantic City, N J., October 9, on "Diagnosis and Management of the More Common Diseases of the Digestive System"

Dr Anthony Bassler (Fellow), New York, N Y., is Vice President of the New York Physicians' Club, a social organization which was recently organized

Dr Frank A Evans (Fellow), Pittsburgh, Pa., was one of the speakers on the program of the Allegheny County Medical Society held at Pittsburgh on October 27. Dr Evans' subject was "Infectious Mononucleosis"

Dr Ray M Balyeat (Fellow), Oklahoma City, Okla., addressed the Third District Medical Society at Lubbock, Texas, October 27-28, on "Allergic Migraine—Diagnosis and Treatment"

The following Fellows of the College addressed the forty-second annual meeting of the Association of American Medical Colleges, which was held in New Orleans, November 30-December 2

Dr Percy T Magan, Los Angeles—
"Rôle of the Medical School in the Development of Character in the Medical Student,"

Dr David J Davis, Chicago—"Cooperation between the College of Medicine of the State University and Other State Departments in Illinois,"

Dr Waller S Leathers, Nashville—
"Teaching of Preventive Medicine"

Dr Horton R Casparis, Nashville—
"Pediatrics Place in General Health Education Program"

Dr Kenneth S Davis (Fellow), Los Angeles, addressed the Los Angeles County Medical Association, November 5 on "Sarcoma of the Stomach"

Dr Charles A Elliott (Fellow), Chicago was among the speakers on the program of the fifty-seventh annual meeting of the Southern Illinois Medical Association No-

November 5-6 Dr Elliott spoke on "Management of Edema"

Dr. Chester S Keefer (Fellow), Boston, Mass, appeared on the clinical program of the joint meeting of the Suffolk District Medical Society and the Boston Medical Library on November 18 Dr Keefer's subject was "Importance of Infection in Arthritis"

Dr. Bernard Fantus (Fellow), Chicago, spoke before the joint meeting of the Saginaw and Bay County (Michigan) Medical Societies, October 28, on "Therapy of Colonic Stasis"

Dr James F Rooney (Fellow), Albany, N Y, addressed the eighth district branch of the Medical Society of the State of New York, October 1, on "Coronary Thrombosis"

Dr J H Elliott (Governor and Fellow), Toronto, has been appointed Professor of History of Medicine at the University of Toronto

Dr Henry S Houghton (Fellow), Dean of the State University of Iowa College of Medicine, is now on tour of the Orient as a member of a commission appointed to appraise and evaluate facts on foreign missions

Dr Joseph H Pratt (Fellow), Boston, has been appointed one of the associates of the Bingham Fund Associates for the Advancement of Rural Medicine, founded by Mr William Bingham, 2nd, of Bethel, Maine, for the purpose of giving aid to the development of medical practice in the State of Maine, and to provide a fund for the advancement of rural medicine

Dr. L Winfield Kohn (Fellow), New York City, acted as Chairman of a meeting of the Baltimore Medical Club of New York, held at the New York Academy of Medicine Building on November 12

Dr J M T Finney, Professor of Clinical Surgery at Johns Hopkins School of Medicine, and Dr Julius Friedenwald (Fel-

low), Professor of Gastro-enterology at the University of Maryland School of Medicine, were the guest speakers

Dr Gerald B Webb (Fellow), Colorado Springs, Colo, delivered a lecture on "The Prescription of Literature," October 21, in connection with a series of lectures on "The Care of the Patient" at the Harvard University Medical School

Dr Stewart R Roberts (Fellow), Atlanta, Ga, gave the second lecture of the series on October 28, his title being, "The Art and Human Nature"

Dr William W Duke (Fellow), Kansas City, delivered an address on allergy, October 13, in connection with the semiannual meeting of the Fort Worth Medical and Surgical Clinics and the meeting of the Northwest Texas District Medical Society

Dr Frank N Wilson and Dr Carl V Weller (Fellows) were among those who assisted in the graduate course arranged by the Department of Postgraduate Medicine of the University of Michigan Medical School and the Michigan State Medical Society, November 3-7 Diseases of the heart and circulatory systems were considered

Dr Weller has recently been elected president of the newly organized Michigan State Pathological Society

Dr Ralph Pemberton (Fellow), Philadelphia, addressed the Jackson County (Mich) Medical Society at their meeting in Jackson, November 5, on "Arthritis"

The following appointments and promotions at the Long Island College of Medicine, New York City, were announced recently

Dr Frank B Cross (Fellow)—Clinical Medicine,

Dr Daniel M McCarthy (Fellow). Assistant Clinical Professor of Medicine,

Dr Paul L Parrish (Fellow), and Dr Murray B Gordon (Fellow) promoted to Professors of Clinical Pediatrics

Dr II Sheridan Bakstel (Fellow), Jersey City, N J, has become Professor Emeritus of Preventive Medicine and Hygiene

Dr Egerton L. Crispin (Fellow), Los Angeles, and Dr Porter P. Vinson (Fellow), Rochester, Minn., were elected President and Treasurer, respectively, of the Association of Resident and Ex-Resident Physicians of the Mayo Clinic and Mayo Foundation at the thirteenth annual reunion of this body in Rochester, October 9

A series of public lectures in the interest of public health education will be offered under the auspices of the Medical Society of the District of Columbia during the fall and winter months. Dr James P. Leake (Fellow) of the U S Public Health Service, delivered the first lecture, October 25, on "Infantile Paralysis." Dr William A. White (Fellow), Washington, delivered the next lecture, November 8, on "Mental Health," and Dr Wallace M. Yater (Fellow), Washington, delivered the third lecture, December 6, on "Physical Fitness at Fifty."

Dr Henry C. Macatee (Fellow), Washington, was a speaker at a symposium on "When Winter Comes," in connection with these lectures, on November 22

Dr Louis H. Fligman (Fellow), Helena, State Director of the American Society for the Control of Cancer, and Dr Ernest D. Hitchcock (Fellow), Great Falls, have been appointed Chairman and a member, respectively, of a Committee of fifteen members of the State Medical Society of Montana for the purpose of formulating plans for an active campaign against cancer in that State

Dr Alfred Stengel (Master), Vice President of the University of Pennsylvania, Philadelphia, delivered an address on "Physical Diagnosis in Relation to Circulatory Conditions" before the meeting of the Association of Surgeons of the Pennsylvania Railroad, October 9, in New York City

GIFTS TO THE COLLEGE LIBRARY OF PUBLICATIONS BY MEMBERS

Acknowledgment is made of the receipt from Dr Edward J. Stieglitz (Fellow), Chicago, of his book "Arterial Hypertension," and of the receipt of a printed copy of a radio address entitled "Government Interference in the Home," delivered by Dr William Gerry Morgan (Fellow), Washington, D C, on Sunday, November 15, 1931, over the network of the National Broadcasting Company

The following gifts of reprints by members to the College Library are acknowledged

- Dr Linn J. Boyd (Fellow), New York, N Y—I reprint,
- Dr L. Winfield Kohn (Fellow), New York, N Y—II reprints,
- Dr William H. Kraemer (Fellow), Wilmington, Del—I reprint,
- Dr Philip B. Matz (Fellow), Washington, D C—I reprint,
- Dr Roy D. Metz (Associate), Detroit Mich—I reprint,
- Dr Oliver T. Osborne (Fellow), New Haven, Conn—I reprint,
- Dr Robert E. Ramsay (Fellow), Pasadena, Calif—I reprint,
- Dr Audley O. Sanders (Fellow), Palo Alto, Calif—5 reprints,
- Dr Walter M. Simpson (Fellow), Dayton, Ohio—I reprint,
- Dr Carl Vischer (Fellow), Philadelphia, Pa—I reprint,
- Dr Frank Wright (Fellow), Chicago Ill—I reprint

Dr John E. Gordon (Fellow), Detroit presented a paper on "Clinical Aspects of Poliomyelitis" before the Gratiot-Isabella-Clare County Medical Society, September 17

Dr James P. Leake (Fellow), U S Public Health Service, was one of the speakers at a symposium on the after-care of poliomyelitis under the auspices of the Bronx County (New York) Medical Society, September 16

Dr Ray W. Kissane (Fellow), Columbus Ohio, used as his title "Relation of Per-

sonal Habits to Adult Heart Disease" in an address before the Knox County Medical Society at Mt Vernon, Ohio, September 24

The Fayette County (Pa) Medical Society held its meeting at Uniontown, October 22 The following Fellows of the College conducted clinics

Dr. Henry L. Bockus, Philadelphia—Gastro-enterology,

Dr. George Morris Piersol, Philadelphia—Internal Medicine,

Dr. Harry B. Wilmer, Philadelphia—Allergic Diseases,

Dr. John Eiman, Philadelphia—Pathology

Dr. Elmer H. Funk (Fellow), Philadelphia, was recently appointed to the Sutherland M. Prevost Chair of Therapeutics, Materia Medica and Diagnosis at the Jefferson Medical College, succeeding the late Dr. Hobart Amory Hare

Dr. Robert B. Wood (Fellow), Knoxville, Tenn., addressed the Hamblen County Medical Society, recently, on "Metabolism and Hypertension"

Dr. Wood also addressed the Roane, McMinn, Monroe and Loudon County Medical Society in Lenoir City, September 3, on "Myocardial Failure"

Dr. Ray C. Blankinship (Fellow), Madison, Wis., addressed the Waupaca County Medical Association at Clintonville, September 24, on "Gastrointestinal Conditions"

Dr. Arthur L. Bloomfield (Fellow), Professor of Medicine, Stanford University School of Medicine, San Francisco, presented the opening lecture of the University of Southern California, September 15, his subject being, "Some Current Problems in Medical Education"

Dr. Lorenz W. Frank (Fellow), Denver, is the Constitutional Secretary of the Colorado State Medical Society

Dr. James G. Carr (Fellow), Chicago, addressed the Morgan County (Ill.) Medi-

cal Society, September 10, on "Rheumatic Heart Disease"

Dr. Ray G. Barrick (Associate), formerly Assistant Professor of Psychiatry at the State University of Iowa College of Medicine, has accepted an appointment at the Institute of Juvenile Research, Chicago Dr. Barrick will be in a charge of mental health work at the Illinois State Penitentiary, Assistant Professor of Criminology at the University of Illinois College of Medicine and Psychiatrist at the Joliet Child Guidance Clinic

Dr. Robert A. Cooke (Fellow), New York City, addressed the joint sessions of the Omaha-Douglas County (Nebr.) Medical Society and the American Congress on Physical Therapy, October 7, on allergy

Dr. Clarence H. Beecher (Fellow), Burlington, Vt., addressed the Grafton County (N. H.), Medical Society in a co-operative meeting with Dartmouth Medical School, October 9, on "Clinical Use of Purgatives"

Dr. Joseph H. Barach (Fellow), Pittsburgh, is the Director of the recently dedicated Falk Clinic of the University of Pittsburgh The Clinic was dedicated on September 28 Doctors Willard J. Stone (Fellow), Pasadena, and Dr. Alfred Stengel (Master), Philadelphia, were guests of honor and speakers at the evening meeting, Dr. Stone's title being "Certain Economic Phases of Medical Practice" and Dr. Stengel's title being "The Clinic and Medical Development" Dr. Barach spoke upon "Aims of the Falk Clinic".

Dr. Frederick G. Speidel (Associate), Louisville, Ky., participated in a symposium on diabetes conducted before the Jefferson County Medical Society, September 21

Dr. Hans Lissner (Fellow), San Francisco, addressed the 57th annual session of the Oregon State Medical Society at Eugene, Oregon, September 24, on "Recent Discoveries in Endocrinology and their Clinical Application"

Dr Horton Casparis (Fellow), Nashville, Tenn, Dr Francis H Smith (Fellow), Abingdon, Va, and Dr George B Lawson (Fellow), Roanoke, Va, all delivered papers before the Southwestern Virginia Medical Society at Marion, Va, September 24-25

At the 32nd annual meeting of the American Roentgen Ray Society at Atlantic City, September 22-25, the following Fellows participated as indicated

Dr Willis F Manges, Philadelphia—
"Primary Carcinoma of the Lung—
Roentgen Ray Diagnosis and Preliminary Report on Roentgen Therapy",
Dr Byrl R Kirklin, Rochester, Minn,
(with Dr C M Moore)—"Benign
Giant Cell Tumors"

Rear Admiral Edward R Stitt (Fellow), formerly Surgeon General of the U S Navy, was retired from active duty in the U S Navy October 1

Lieut Comdr John H Chambers (Fellow), Medical Corps of the U S Navy, has been transferred from the Public Health Service of Haiti to the Naval Hospital, League Island, Philadelphia

Dr Francis E Seneor (Fellow), Chicago, conducted a dermatologic clinic in connection with the Logan County Medical Society's meeting at Lincoln, Ill, September 24

Dr William W Duke (Fellow), Kansas City, Mo, delivered a paper on "Allergy as Related to General Medicine" before the Dubuque County (Iowa) Medical Society, September 8

Dr S Marx White (Fellow and President), Minneapolis, addressed the Linn County (Iowa) Medical Society at Cedar Rapids, September 10, on "Subacute Bacterial Endocarditis"

Dr Philip F Barbour (Fellow), Louisville, Ky, was elected President-Elect of the Kentucky State Medical Association at its annual meeting at Lexington, September 7-10

Dr Stuart Pritchard (Fellow), Battle Creek, and Dr James D Bruce (Fellow), Ann Arbor, were among those chosen by Governor Brucker as members of an Advisory Commission to coordinate child welfare work in Michigan

Dr Frederick G Banting (Fellow), Toronto, was one of the speakers at the annual convocation of the University of the State of New York, held in the State Education Building, Albany, October 15-16

Dr I M Rabinowitch (Fellow), Montreal, participated in the symposium on the liver and spleen, held under the auspices of the Vermont State Medical Society at Rutland, October 8-9

Dr Louis F Jermain and Dr John J McGovern (Fellows), both of Milwaukee, were the recipients of the gold seal of the Wisconsin Medical Society at its recent annual meeting. The gold seal is an honorary award presented annually

Dr Otho R Fiedler (Fellow), Sheboygan, was installed as President of the Society for the coming year

OBITUARIES

DR BRADFORD CHURCHILL
LOVELAND

Dr. BRADFORD CHURCHILL LOVE-
LAND (Fellow), Syracuse, N Y, died
June 25, 1931, of myocarditis, age
sixty-nine years

Dr. Loveland was born at Newark,
N Y, and attended Newark Acade-
my, Susquehanna University, and
later the University of Michigan Med-
ical School, from which he received
the degree of Doctor of Medicine in
1888. He pursued postgraduate study
at the New York Post-Graduate Med-
ical School. He was a lecturer on
medical jurisprudence at the Syracuse
University School of Law from 1917
to 1927. His practice was limited to
neurology and psychiatry. During
1898-1899 he served as Medical Su-
perintendent of the Clifton Springs
Sanitarium. Soon thereafter he went
to Syracuse, where he became Neu-
rologist for the Hospital of the Good
Shepherd and the Syracuse Free Dis-
pensary. For several years he served
as Chief of the Bureau of Psychiatry
of the Syracuse Department of
Health, and was Neurologist to the
Syracuse University Hospital. Dr.
Loveland was a member and trustee
of the Syracuse Academy of Medi-
cine, a member of the Onondaga Med-
ical Society, a member of the New

York State Medical Association, a
Fellow of the American Medical As-
sociation, and had been a Fellow of
the American College of Physicians
since April 15, 1920. He was the
author of a considerable number of
articles published in various medical
journals.

DR THEODORE LEACRAFT
HEIN

Dr THEODORE LEACRAFT HEIN
(Associate), New York City, died
September 25, 1931 of heart disease,
aged 52 years.

Dr. Hein was a graduate of the Col-
lege of Physicians and Surgeons of
Columbia University, 1905. He did
postgraduate study in medicine at St.
Bartholomews, London, Charité of
Berlin, and at the Allgemeines Kran-
kenhaus of Vienna. He was formerly
instructor at the New York Post-
graduate Hospital, and assistant in the
Vanderbilt Clinic and the Stuyvesant
Polyclinic. At the time of his death
he was physician-in-charge to the
Queens Plaza and Ridgewood Clinics,
Department of Health. Dr. Hein was
a Fellow of the American Medical
Association, a member of the Medical
Society of the County of New York,
and had been an Associate of the Col-
lege since 1921.

Quinidine Therapy in the Treatment of Cardiac Irregularities Due to Hyperthyroidism*†

By J P ANDERSON, M D, F A C P, *Cleveland, Ohio*

QUINIDINE sulphate has rightfully earned a permanent place in the treatment of cardiac irregularities, especially those which are secondary to hyperthyroidism. The heart rhythm naturally tends to return to normal after thyroidectomy alone but by the addition of quinidine therapy the number of restorations to normal rhythm can be increased greatly.

The percentage of cases in which the heart rhythm returns to normal after thyroidectomy alone depends chiefly on the following factors: (1) the duration of the irregularity of the heart rhythm previous to operation, (2) the degree of arteriosclerosis and myocardial degeneration, (3) the age of the patient; (4) complications, such as focal infections.

In 1927, I reported a series of 75 cases of hyperthyroidism in nearly all of which auricular fibrillation had been present for a long time, and in several cases extensive cardiac failure had been present for several years. Our follow-up records showed that in only 32 per cent of these cases did the rhythm return to normal. Later in

the same year I reported another series of 75 cases which included all patients who had shown any auricular fibrillation while in the hospital. Sixty per cent of this second series acquired normal rhythm. Quinidine was used three times. In a later series of cases the normal rhythm was restored in 66 per cent.

At that time quinidine was not being used directly after operation, and the difficulty of instituting treatment a few weeks later led to the omission of its use in a large number of cases. Also, it was found that our attempts to restore normal rhythm a few weeks or months after thyroidectomy frequently met with failure. This fact led to the institution of quinidine therapy while the patient was still in the hospital. At first it was administered on the sixth or seventh postoperative day, and no embolic accidents resulted from its use. However, by that time the patient was out of bed and ready to go home and did not wish to remain in the hospital for two or three days longer in order to undergo treatment for the heart.

We then tried instituting quinidine therapy during the decline of the postoperative reaction, that is, on the third or fourth postoperative day. The good results of this experiment would seem to indicate that this is the best time to

*Presented at the Baltimore meeting of the American College of Physicians, March 26, 1931.

†From The Cleveland Clinic, Cleveland, Ohio.

institute treatment as the patient is still in bed and his stay in the hospital need not be prolonged after he is able to be up

No attempt is made to restore the heart to a normal rhythm before operation because it is seldom successful, and if it does succeed, auricular fibrillation is likely to recur at the time of the operation. For this reason quinidine is seldom used after a first lobectomy.

At the Cleveland Clinic we have adopted the following plan of management of patients with hyperthyroidism in whom abnormal heart rhythm is present.

All patients in whom auricular fibrillation is still present on the third post-operative day are reported. A test dose of quinidine is administered to these patients and if no ill effects are noted they receive 5 grs of quinidine sulphate every four hours, day and night, for twenty-four hours. The pulse is counted before the administration of each dose and if the rhythm is found to be regular, medication is discontinued. If no improvement is noted after twenty-four hours treatment, 5 grs of quinidine are given every three hours for twenty-four hours and then every two hours for twenty-four hours, and occasionally for forty-eight hours.

In the majority of cases normal rhythm will be restored after a few doses, but occasionally two or three days' treatment will be necessary. In one case we found no change after the third day, and treatment was continued on the fourth day. Two hours after the last dose of quinidine had been administered, normal rhythm was restored.

In the case of one of our patients,

a woman 46 years of age, a very interesting result from the use of quinidine was noted. Symptoms of hyperthyroidism had been present for two years previous to thyroidectomy. The thyroid tissue showed diffuse hyperplasia. After thyroidectomy had been performed, the general condition improved greatly but the patient was nervous and her heart continued to fibrillate. The administration of digitalis did not slow the ventricular rate to normal although it reduced it from 130 to 100. The patient's basal metabolic rate was +23, suggesting that residual hyperthyroidism was present. The administration of iodine had no effect on the heart action. Inasmuch as there was no recurrent enlargement of the thyroid gland, quinidine therapy was instituted with the result that the heart rhythm became normal, the nervousness disappeared, and the patient was able to return to work. Since that time, a year ago, there has been no recurrence of symptoms.

A very few patients are sensitive to quinidine. In one of our recent cases, the patient experienced a great deal of distress during one night after her third dose of 5 grs of quinidine. She became dyspneic, nauseated, flushed, perspired a great deal, and experienced fear of death. It can not be stated definitely whether this condition was due to the effect of the quinidine or to a pulmonary embolus but the fibrillation persisted, and the patient refused further treatment.

In the case of another patient quinidine therapy had to be discontinued on account of nausea and vomiting. Its administration was attempted a second time with a similar result.

The question is frequently asked—will auricular fibrillation recur after the heart rhythm has been made regular by the administration of quinidine? We know of only one case in which there was a recurrence of auricular fibrillation after a thyroidectomy had restored the heart rhythm to normal,

in death. For several days the temperature varied between 103° and 105.5° and the pulse rate varied between 130 and 160, but at no time was any auricular fibrillation present.

In table I is shown the effect of thyroidectomy on auricular fibrillation.

Table II shows the results of the use

TABLE I

	Regular after thyroidectomy	Irregular after thyroidectomy
Series I	24	51
75	32%	68%
Series II	45	30
75	60%	40%
Series III	112	73
185	60.5%	39.5%
Series IV	26	31
57	45.7%	54.3%

TABLE II

	Treated with quinidine	Regular after quinidine	Irregular after quinidine
	late	10	6
	16	60%	40%
	prompt	22	1
	23	96%	4%

and in the group in which quinidine therapy was instituted there has not been any recurrence of auricular fibrillation.

In one case, a patient was given quinidine on the fourth postoperative day and the heart rhythm became regular. The following day auricular fibrillation was again present. Upon inquiry it was found that only a lobectomy had been performed. It is my opinion that if auricular fibrillation recurs after quinidine has been administered postoperatively, residual or recurrent hyperthyroidism may always be suspected.

In another case the patient was given quinidine about six months after a thyroidectomy had been performed. After the third day of treatment the heart rhythm was found to be restored to normal. A few months later an abdominal operation was performed, followed by a general peritonitis resulting

in death. For several days the temperature varied between 103° and 105.5° and the pulse rate varied between 130 and 160, but at no time was any auricular fibrillation present.

of quinidine in a series of cases with persistent auricular fibrillation after thyroidectomy. In sixteen cases quinidine therapy was instituted during a period of from several weeks to several months following operation, and of this group the normal heart rhythm was restored in 60 per cent of the cases while in 40 per cent the rhythm remained irregular. In 1930 a follow-up record was made of 57 cases following thyroidectomy. Quinidine therapy was instituted promptly in the treatment of 23 patients resulting in the restoration of the normal heart rhythm in 96 per cent.

When auricular fibrillation is still present after the fourth postoperative day, it usually persists unless quinidine therapy is instituted, and our experience has demonstrated that better results are obtained if quinidine is given during the decline of the postoperative reaction.

AURICULAR FLUTTER

In my experience the complication of auricular flutter associated with hyperthyroidism has been encountered only three times, and in two of these cases auricular fibrillation and auricular flutter were present alternately. Of the three patients who were treated with quinidine, normal heart rhythm was restored in two cases but not in the other, although a very thorough course of quinidine therapy was given. Auricular fibrillation was present in the latter case and after the administration of quinidine the heart rhythm became regular but the pulse rate remained at about 100. This condition was unusual, as the pulse rate after the heart rhythm has been restored to normal is usually about 80. An electrocardiogram showed a flutter which la-

ter was unaffected by four days' treatment with quinidine.

CONCLUSIONS

1. Quinidine sulphate is a very useful drug for the restoration of a normal cardiac rhythm if a thyroidectomy alone fails to achieve this result.
2. Observations over several years show that the maximum benefit is obtained when the drug is given on the third or fourth postoperative day.
3. A very few patients are sensitive to quinidine, thus prohibiting its use in such cases.
4. By adding quinidine therapy after thyroidectomy when auricular fibrillation is still present, a normal cardiac rhythm will be restored in about 96 per cent of cases.

Tachycardia*†

BY CHAS W BARRIER, M D, *Fort Worth, Texas*

TO a noted cardiologist of the previous generation, paroxysmal tachycardia was merely a clinical curiosity. To the few who have attacks prolonged into weeks and even years and who suffer acute heart failure when an extra burden such as a cold and cough is put upon them, it is a tragedy.

I am limiting my subject to auricular and nodal tachycardia. The literature does not indicate the number subject to these attacks. This paper is based upon a study of twenty-six proven cases occurring in about four thousand general admissions in three years. If to this twenty-six are added those who gave histories of paroxysmal acceleration, but who were without electrocardiograms, the incidence of paroxysmal tachycardia would be higher than is generally thought.

ETIOLOGY

Experimentally, Lewis¹ has produced attacks by stimulation of the vagus nerve and by ligating the coronary artery.² Boorman⁴ destroyed the sinus node with radon, but this was often eventually followed by a rhythm

simulating a typical sinus rhythm. Bouchut³ reports a case with an infarct in the region of the sinus node. Clinically, Major⁵ found acute and chronic myocarditis in the auricle of a person dying in an attack, and Anderson⁶ reports auricular tachycardia as a complication of diphtheria. Attacks are not unusual in cases of mitral stenosis, and they are likely to occur in the course of heart failure from various causes. Kern⁷ reports a case occurring on inflation of the Fallopian tubes with air. It is interesting to conjecture that the attack was due to air embolism of the coronary artery, basing our conjecture upon the frequency of tachycardia after occlusion and of the occurrence of coronary embolism when air enters the circulation.

An important exciting cause of tachycardia is drugs, chief among which is digitalis, as pointed out by Luten.⁸ Howard⁹ calls our attention to the great danger of excessive digitalis producing a coexistent auricular and ventricular tachycardia. Galli,¹⁰ contrary to the experience of Lewis, insists that atropine can excite paroxysms. Adrenalin will frequently cause attacks in susceptible patients. Terrell¹¹ has observed nodal attacks after ephedrine in an asthmatic who had not previously had attacks. Numerous other drugs, as well as mineral salts, may provoke

†From the Harris Clinic Hospital, Fort Worth, Texas.

them In spite of the efficacy of quinine in stopping attacks, Korns¹² labels it as an excitant of tachycardia.

The great majority suffering from tachycardia are free of cardiac pathology. Cair¹³ stresses its occurrence among the nervous type, and Thomas¹⁴ reports cases occurring in persons subject to other neuroses such as migraine.

Two of my cases had early exophthalmic goiter, one had rheumatic endocarditis, a few had mild hypertension, and several fell in the sclerotic heart group, but most were without heart lesions. Two were conspicuous because of their athletic prowess. Yet, even these had marked nervous instability, one of them blushing, trembling and turning giddy when called on in class.

Colgate¹⁵ reports cases occurring in early infancy, and while cases occur at any age, the literature would indicate the prevalence of tachycardia in the fifth and sixth decade. My cases fall roughly into two age groups, the first is that of adolescence in which the individuals have excessive variability of their sinus rate and an increased emotionality suggesting in many a degree of hyperthyroidism. The other group consists mostly of women about the menopause who are often overworked, poorly nourished, suffering from the effects of purgatives and flatulence, and frequently from migraine attacks. In both, attacks are precipitated most often by unusual exertion or emotions.

MECHANISM

Lewis¹⁶ teaches that the mechanism of an attack is repeated ectopic systoles, a different mechanism from flutter which is a circus movement. Colgate¹⁵ observed cases in which it was difficult

to tell the difference in electrocardiograms between cases of tachycardia and flutter. He concluded that the mechanism of tachycardia was a circus movement varying only in degree from that of flutter. One would conclude from Crawford's¹⁷ case in which there was a shift of the pacemaker from the sinus to the lowest part of the A-V node that the attacks are neurogenic. Willius dismisses the idea that toxins make these hearts unusually susceptible to nervous influences. The view of Otto,¹⁸ arrived at from the action of drugs on the onset and arrest of attacks, that the mechanism is a circus movement, seems the most plausible.

PROGNOSIS

To Willius¹⁰ the prognosis depends upon the underlying heart pathology and upon the rate and duration of the attacks. Many texts speak of the prolonged attacks ending in congestive heart failure and death. Carr¹³ believes that death is a rare termination. One of my patients who had mitral stenosis and a crippled myocardium entered the hospital on the thirteenth day of an attack, cyanotic, with a bloody sputum and general anasarca. Recovery took place. Another who endured attacks lasting for months with a rate of about 160 without trouble except for a limitation of his efforts, developed acute congestive heart failure after a cold and cough, and death was imminent for days. The usual rate of 160 increased to 200 and the mechanism from auricular to nodal.

Prognosis, however, does not concern itself so much with mortality as with incapacity. This incapacity in short attacks varies from concern over

the rate and unpleasant palpitation to more serious symptoms such as cardiac pain,²⁰ syncope and convulsions,²¹ but as a rule the general comfort and lack of dyspnea are striking when the excessive rates are considered. Nodal tachycardia causes more symptoms than an auricular attack of the same rate due, no doubt, to poorer filling of the ventricle and the contraction of the auricle against a closed valve. One patient with a mild exophthalmic goiter, B M R +35, experienced no real inconvenience from a sinus rate of 150, but complained of severe heart pains, violent palpitation, nausea, vomiting, and fainting at a sudden onset of nodal tachycardia with a rate of only 160.

In some patients, prolonged duration is the chief disturbing factor. Most authors report the time as only a few minutes and at the longest as only a matter of weeks. Cohn speaks of attacks extending into years, and Gilbert²² reports a case which he considered permanent. One of my cases lasted seven days, one thirteen days, one six weeks, one three years save for one thirty minute interval, and one case for the past six years has been in permanent tachycardia except when under the effects of digitalis. The case lasting three years had for years been subject to frequent short attacks in which there was fainting, but after the onset of permanent tachycardia the rate dropped to between 160 and 180 and she lived in comparative comfort. The other case in which the tachycardia was permanent was comfortable while at quiet occupations, but on strenuous exercise the rate would rise to above 200 with distressing dyspnea.

These patients with prolonged attacks, unless victims of obvious heart lesions, have suffered no cardiac deterioration from the rate.

DIAGNOSIS

The characteristics of paroxysmal auricular and nodal tachycardia upon which a diagnosis is made clinically are the abrupt onset and arrest, repetition of attacks, constancy of the rate throughout an attack, the much quoted observation of Feil²⁴ of the absolute regularity of rhythm, and the effect of vagus stimulation in arresting an attack.

It is not unusual, however, for auricular attacks to begin at rates above 180 and finally drop to 140 or less. The rate may increase because of exercise or atropine, and the rhythm may be irregular due to vagus effect or drugs, digitalis in one case producing a bigeminy, and a fast sinus rate may unnoticeably pass into an auricular tachycardia of the same rate by a gradual shift of the pacemaker.

TREATMENT

Treatment consists in removing the cause, arresting and preventing attacks. Two of our cases were permanently cured by iodine and thyroidectomy. Most attacks are short and end spontaneously. Often rest, chloral and bromides are necessary. All stimulants such as camphor should be prohibited.

Vagal stimulation has been the most popular mode of arrest. Fiessinger²⁵ has obtained this end by depriving the patient of air causing forced respiration. Wolffe²⁶ stops attacks by intravenous calcium, the action being very similar to quinidine, while Steppe²⁷

has made use of the vagotonic action of cholin. Wilson²⁸ publishes cases showing arrest by intravenous digitalis. Eakin²⁹ would use digitalis with caution in tachycardia unless the attack is known to be supraventricular because of its danger in ventricular tachycardia, especially in the presence of coronary occlusion.

Bodin³⁰ first used quinidine, showing that it would stop some attacks, while only slowing the rate in others, and Ihescu³¹ publishes a case in which the rate was slowed to the normal rate without a change of mechanism. Sprague³² believes half the cases can be arrested by quinidine and shows its value in preventing attacks.

We have treated eight patients in repeated attacks with digitalis either with massive doses by mouth or intravenously. Arrest was obtained in six cases, and was felt in all probability to be due to the digitalis. In ten cases we have used quinidine sulphate either by mouth or vein and arrested attacks in nine. There were five of these cases that responded both to digitalis and quinidine. Two patients, one because of apparently permanent tachycardia or frequent attacks, were rationed on quinidine for a year. Attacks were certainly warded off, but the dose had to be increased from a start of six grains a day to twenty-one. Even at this dose attacks appeared and the patients complained so vehemently of the drug that it was withdrawn. These two cases and one other case of permanent tachycardia were kept on digitalis for the greater part of two years. Though large doses, four to six grains a day, were often required, the results on the whole were more satisfactory.

MODE OF ACTION OF DRUGS

As the mode of action of drugs in stopping attacks is of supreme interest, careful records of the action of digitalis and quinidine given intravenously were made in the following cases.

Case I A woman of thirty-nine, whose examination, made later, revealed no finding varying from normal except a blood pressure of 148, entered the hospital one and one-half hours after the onset of an attack, in circulatory collapse. She had a nodal tachycardia, rate 255. Three hours after the onset 8 cc of digalen were given by vein, and in seven minutes the rate was slowed to 220. After a second dose of 6 cc, sinus mechanism was restored, rate 90. (See figure 1.)

Case II A vigorous man of thirty-two without any heart lesion came to the Clinic because of attacks of tachycardia which had come at frequent intervals since age sixteen. They were usually ushered in by exertion or emotion and lasted from one to fourteen hours. It always required a period of rest before cessation of an attack.

On the second morning an attack of nodal tachycardia, rate 260, was induced by ten minutes of vigorous exercise. This attack was allowed to subside spontaneously. After about half an hour the rate had slowed gradually to 200. In another hour the rate suddenly dropped from 200 to 90. During the next twenty minutes there was frequent repetition of the fast rhythm, but finally the slow rate was established.

On the next morning another attack was induced. In one minute after the injection of only 0.05 gram of quinidine sulphate the rate had appreciably slowed. A tracing one minute after an injection of 0.1 gram of quinidine sulphate showed a sinus rhythm with a rate of 150, which in four minutes had dropped to 110. The total dose was 0.25 gram, and the total time thirty-four minutes. (See figure 2.) The mode of arrest was quite a contrast to the spontaneous one. The total dose might have been given at one time and no doubt arrest would have been sudden.

A third attack was induced the next morning. In one minute after 5 cc of digifolin, the rate had dropped from 255 to 240 and at the end of seven minutes to 195, and at the end of thirty minutes after a total dose of 20 cc the rate was 180 and markedly irregular. Three minutes later normal rhythm ensued before inversion of the T-wave. (See figure 3)

Case III A woman of twenty-one without a heart lesion came for examination in 1928 saying that five years before she had had her first attack of fast heart. These attacks became more frequent and extended, so that for the last three years she had been in a constant attack. Nodal tachycardia, rate 160, was found. Quinidine sulphate caused a normal rhythm of 100. As this gave so much relief she was kept

on quinidine for the year of 1928. At first six grains a day were sufficient, but by the end of the year twenty-one grains were necessary and attacks became so frequent and the effects of the large doses so annoying that quinidine was discontinued.

It was then found that digitalis in large doses would ward off attacks, and for 1929 and part of 1930 she stayed on digitalis. While attacks occurred she felt that her condition was distinctly better than when on no treatment and on quinidine, but in June, 1930, she stopped digitalis and found that she was free of attacks unless she lost sleep or overworked. When attacks occurred, they were more violent and had to be stopped with quinidine.

Five hours after the onset of an attack on January 18, 1931, she entered the hospital before any treatment. Nodal tachycardia,

FIG 1 Nodal tachycardia Arrested with digitalis

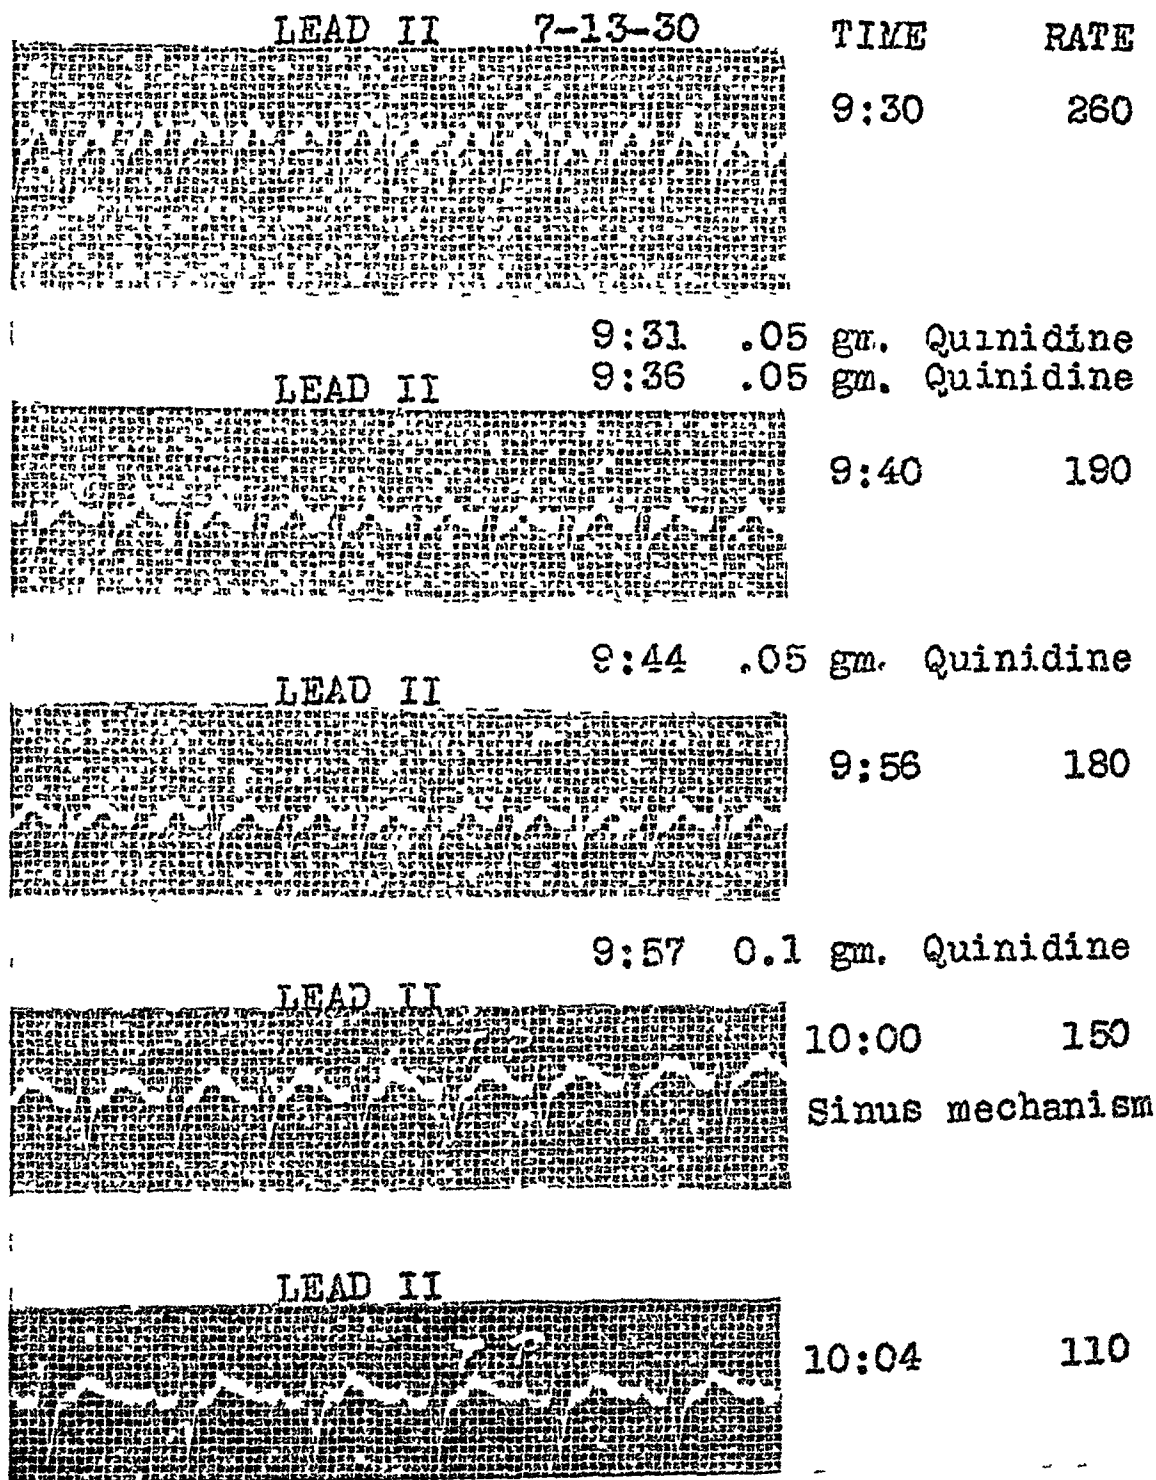

FIG 2 Nodal tachycardia Tracing every three minutes, string under constant vision

rate 195, was present Three minutes after the injection of 0.2 gram of quinidine, normal rhythm resulted, rate 145 In forty minutes this had gradually slowed to 110 (See figure 4)

Nine days later she again entered the hospital, twelve hours after the onset of

Case II A boy of twenty-one, robust in every respect and without heart lesion, first came under observation four years ago His physician had records showing a tachycardia for the previous two years His was an auricular tachycardia, rate 160 to 190 Repeated efforts with quinidine failed

FIG 3 Nodal tachycardia Digitalis Tracings every three minutes, string under constant vision

tachycardia, the rate being 180 Three doses of 4 cc each of digalen were given by vein in thirty-three minutes After the first dose there was a gradual slowing so that after fifty minutes the rate had dropped to 125, but nodal rhythm persisted Seven minutes later there was a sudden drop of rate to 50, irregular, but of sinus mechanism (See figure 5)

to effect an arrest Since his first admission he has been in tachycardia except when under digitalis It took about 25 to 30 cc of the tincture to arrest an attack, but the tachycardia reappeared in about five days if digitalis was left off Large maintenance doses were required and even then after a few days a fast sinus arrhythmia with relapses to auricular tachycardia occurred

After leaving off digitalis for three weeks he was admitted in an attack, rate 170, of two weeks duration. Eight-tenths of a gram of quinidine sulphate was given in divided doses by vein over a period of one and one-fourth hours. Though unmistakable evidence of intoxication was present, sinus mechanism was not established, but the rate was slowed. Vagal stimulation then caused

After leaving off digitalis for a month he again entered the hospital in auricular tachycardia, rate 145, duration three weeks. After exercise the rate rose to 160. He was then given atropine, $1/25$ grain. During the next thirty-seven minutes he was given 8 cc of digalen and $4/150$ grain of atropine. Ten minutes later he had a sinus mechanism, but in fifteen minutes more this had changed

FIG 4 Nodal tachycardia Quinidine sulphate Tracings three to seven minutes, string constantly observed

no intermission, though previously it had (See table I)

The next day with a rate of 170 a total of 16 cc of digifolin was given by vein in divided doses during a period of thirty-four minutes. Slowing of the rate began early, and in thirty-six minutes sinus mechanism ensued with the fairly slow rate of 95. The change in rate was so gradual that it was impossible to tell from movement of the string when the change of mechanism took place, though the patient knew when it occurred by the relief of palpitation (See figure 6)

back to an auricular rhythm which persisted until the next day, when he had a slow sinus rhythm. There can be no doubt but that he had enough atropine to block the vagus and digitalis enough to cause full effect (See figure 7)

COMMENT

In two of the above three cases in which quinidine was used there was an arrest of the attack. In both the mechanism was possibly nodal. In all three there was a definite slowing of

the rate of the attack. In the two in which the attack was arrested, the sinus rate was at first almost as fast as the paroxysmal rate. Assuming that the mechanism of paroxysmal tachycardia is a circus movement, quinidine slows the rate by slowing conduction and arrests the attacks by increasing the refractory period of the auricular muscle. In the two cases reacting to quinidine, in one in which quinidine was inactive, and in one in which quinidine was not used, digitalis slowed the rate and arrested the attack as did quinidine. It is difficult to explain the action of digitalis in slowing the rate

for in other examples of circus movement, namely flutter, it increases the rate. By its effect through the vagus, digitalis may decrease the conduction time out of proportion to the decrease in the refractory period and end circus movement, or it may end circus movement by its effect on the muscle in lengthening the refractory period.

In one case digitalis failed to arrest permanently an attack after complete paralysis of the vagus by atropine. It would seem, therefore, that digitalis arrests the attacks by action on the vagus. With atropine, digitalis slowed the auricular rate.

SUMMARY

The important features in a series of twenty-six cases of supraventricular tachycardia are noted. Cases of unusual duration are reported, one case having an attack lasting three years, another being in a permanent attack for nearly six years unless treated.

Quinidine in most cases of supraventricular tachycardia is the more desir-

able drug for arresting an attack, though in the presence of heart failure digitalis will act and may be the drug of choice. In two cases where quinidine was continued for a year, it had to be used in increasing doses.

Continuous digitalization has been extended over periods as long as one and a half years. While the continuous use of digitalis is to be preferred over

quinidine, the drug must be used in such large doses that toxic effects appear.

Both digitalis and quinidine will slow the rate and arrest the attacks in the same patient. Until the mechanism of these attacks is better known, the mode

of action of drugs cannot be explained.

Digitalis did not arrest an attack in a patient who had received 1/15 grain of atropine.

Both digitalis and quinidine act well by mouth, and few cases need the drugs by vein.

Answer "Yes" or "No"

"NATURALLY, from the very nature of its objective, the hypothetical question must be a biased and one-sided affair in order to be of value as a piece of evidence carrying weight with those deciding the case. It is just this one-sidedness which frequently taxes the physician-witness's conscience in fairly answering by the generally requested 'yes' or 'no'. No medical expert can be compelled to answer either positively or negatively a hypothetical question that is based either wholly or in part upon subject matter so arranged that he cannot conscientiously give the reply asked for. Furthermore, a medical expert's answer to the effect that he does not know, is also expressing an opinion, and is considered a reasonable and logical reply thereto. The lawyer, to be sure, usually requests hypothetical questions to be answered in the affirmative or negative by monosyllables, *but it nevertheless remains the inalienable right of the witness to testify according to the dictates of his conscience in harmony with his oath as a witness, and not at all according to the preconceived notions of a lawyer propounding a debatable question.*"

The Response of the Cardiovascular System to Respiratory Strain: A Measure of Myocardial Efficiency*

BY ALLAN EUSTIS, B S , M D , F A C P , *New Orleans, La*

THE importance of determining the functional capacity of the myocardium in organic heart disease has engaged the attention of cardiologists for many years, but in 1922, Brittingham and White,¹ after a careful study of the tests then in use, concluded that there was no satisfactory test for cardiac function. During this same year Frost² arrived at the same conclusion, and at the annual meeting of the Association of Life Insurance Medical Directors of America, he described a new cardiorespiratory test developed in collaboration with Dwight, which was being used by the New England Life Insurance Company in evaluating cardiac cases. A report of this meeting was not published in the current medical journals which probably accounts for its being overlooked by the profession at large, but subsequent publications by Frost³ should have augmented the scant attention which it has received, especially at the hands of the cardiologists, although Herrmann⁴ in 1927 states, "The cardiorespiratory test as described by Frost is certainly a most

promising clinical method of estimating the functional state of the circulatory system." Several of my publications⁵ bear evidence that its clinical value has been appreciated by me since 1924, and at the Sixth Annual Congress of Anesthetists in Washington in May, 1927, I suggested that a simplification of Frost's original technique, utilizing only steps 6, 7 and 8, would result in a simple test whereby anesthetists could judge the patient's cardiovascular state before an anesthetic was given. Later, I published⁶ a description of the modified technic, which I have been using for the past five years.

In following the progress of cases of chronic myocardial insufficiency the cardiorespiratory test has been of inestimable value to me, while the therapeutic indications have often been predicated upon the patients' response to this test, as well as the diagnosis being suggested by same. Common sense should prevail in the interpretation of the response, as Schmitz⁷ so aptly suggests in a resumé of the value of various heart function tests, when he calls attention to the fact that most investigators have made the error of employing the various tests as heart tests rather than as tests of the person with

*Presented at the Baltimore meeting of the American College of Physicians, March 20, 1933.

heart disease. The cardiorespiratory test depends upon the physiological fact, that increase in intrathoracic pressure caused by forcible expiration, results in a rise in systolic blood pressure, a subsequent fall, and then a rise above that of the initial systolic blood pressure in an individual with a normal cardiovascular system.

A study of 160 responses on 125 cases taken from my office files, forms the basis of this paper, no attempt being made to review other cardiac functional tests. However, attention should be given to a recent combination test devised by Mackenzie⁸ and his co-workers in the Medical Department of the Prudential Life Insurance Company, which is called the flarimeter test, this being an ingenious combination of the step test, cardiorespiratory test, and the ability to hold the breath after exercise. I have had but little personal experience with this test, but it appears too complicated for general clinical use. Yet, the spirometer used in the test for expiration is probably preferable to the simplex spirometer, which as an accurate measure of vital capacity, is admittedly open to criticism.

A letter recently received from Frost, who is Medical Director of the New England Mutual Life Insurance Company, where the cardiorespiratory test has been in use in his department since 1922, will bear quoting in full. He writes:

"We are still using the cardiorespiratory test routinely in our work and think as much of it as ever. Our experience is now based on from 8,000 to 10,000 such tests. We have just finished investigating 5,000 individuals whom we have accepted upon the basis of the test and are satisfied that it provides us with the means of controlling

the mortality in the circulatory cases at least for a period of eight years, which is, of course, the period of our present study. We still believe that it gives us an idea of the ability of the circulation at the time of examination which we can obtain in no other way. You may be interested to know that in the 5,000 cases which we have just investigated, the gross mortality of the group was 42 per cent of the American Experience Table. Analyzing this material more carefully, we find that in all the cases in which the reaction of the test has been a straight normal we have a mortality of 30 per cent. On the other hand, in those cases in which the reaction tended to abnormality, in particular, of the hyperactive type, the mortality mounts to 75 per cent. In other words, with an average mortality of 42 per cent, in the presence of a perfectly straightforward, normal cardiorespiratory test, we have a mortality of 30 per cent and in the presence of the tests bordering upon abnormality we have the higher mortality of 75 per cent. From our point of view, therefore, basing our results on mortality figures, our experience has been entirely satisfactory and so far as we know better than any hitherto obtained."

The modified technic of the cardiorespiratory test which I have adopted and used extensively for the past five years is as follows. After physical examination of the patient and recording of results, the systolic and diastolic pressure is taken by the auscultatory method with the patient seated, the pulse rate being counted at the same time by auscultation over the brachial artery. The pressure in the cuff is then released and the patient told to expire through the spirometer after full inspiration, cautioning him to watch the pressure gauge and keep the pressure uniform at 20 mm of mercury. The systolic pressure is taken before the patient inhales, and after expiration has been completed, the maximum systolic pressure being recorded. With-

*Negative response

out releasing pressure in the cuff, the needle of the spirometer is turned to zero, the systolic pressure is again taken and the patient again instructed to inhale fully and expire through the spirometer as before. Three successive readings are then made, corresponding to steps 6, 7 and 8 in Frost's technic. If it is evident that the patient has not expired his full vital capacity, a second test should be made after cautioning him to inhale and expire fully, or, perhaps only a fourth expiration may be necessary.

The results may be plotted as a curve, the change in millimeters of mercury in blood pressure obtained after each expiration representing the response, and the change in millimeters in the blood pressure obtained just prior to each inspiration representing the base line. A normal response should result in an increase of systolic blood pressure after the third expiration of from 30 to 40 mm. A failure to respond, in my experience, denotes a weakened heart muscle. A falling base line is invariably associated with great dilatation of the heart. The test should not be tried on any individual with marked dilatation of the heart, as I have seen in my early experience a near approach to syncope result in such instances, while in others marked cardiac distress has been observed. The test should be used with caution, also, on patients with a history of anginal attacks, as well as on cases of arterial hypertension. These precautions are needful with any other cardiac function test, but, I believe the danger from the cardiorespiratory test is less than with most cardiac tests involving a strain on the heart muscle.

The test is especially valuable in the study of chronic myocardial insufficiency, and in the protocol, where the diagnosis of myocarditis is recorded, it must be interpreted as the commonly used term to express myocardial degeneration, in which there is usually evidence of myocardial insufficiency. In numerous instances, however, the electrocardiographic tracings denoted myocardial disease, while both clinically and by the cardiorespiratory test, the heart muscle was able to function normally. An examination of the protocol will at once be convincing that the test has been of considerable value to me in clinical evaluation of cases, and a discussion of interesting phases of some cases is in order.

DISCUSSION OF PROTOCOL

A study of the protocol shows that of the 160 responses, 56, or 35 per cent, have been listed as poor, i.e., responses below 20 mm, 40, or 25 per cent, as fair, i.e., 20 to 30 mm, and 64, or 40 per cent, as normal, i.e., above 30 mm. These correspond to the interpretations of Frost as, below normal, low normal, and normal respectively. Further examination will also reveal the fact that some responses were recorded as normal, which on strict interpretation should have been classified as hyperactive, the reason for this being, that I have been particularly interested in detecting weakened heart muscles, rather than evaluating the cases from an insurance standpoint. Of the 56 poor responses, only five, or 21 per cent of the total (numbers 22, 26, 34, 87 and 124) failed to exhibit other evidences of a weakened heart muscle after the test. The condi-

tions present in cases numbers 22, 26 and 34 are those often associated with myocardial changes; while no 87 was the response of a man 64 years of age, at which time of life a weakened heart muscle is by no means rare. So it is not illogical to suppose that in these cases the poor response was due to weakness of the heart muscle rather than to vasomotor phenomena. No 124 was obtained on an asthenic individual, who is easily fatigued, with no demonstrable evidence of any focal infection, and with no manifestation of myocardial lesion. His skeletal muscles are flabby, and accepting Starling's idea, that the physiology of the heart muscle as regards its ability to contract and perform work is identical with that of the skeletal muscles, it may be assumed that in this instance, also, the myocardium was weak, though no other symptoms of myocardial insufficiency could be elicited.

In all of the other 51 poor responses, the appearance of a murmur at the apex, or the accentuation of a pre-existing murmur, or an increase in pulse rate, cough or dyspnea were detected after strain was put upon the heart by the test. Some cases (numbers 13, 21, 90, 91 and 92) responding poorly at first examination, responded to the test normally after the heart muscles had been toned up by graduated exercise, and other therapeutic measures. This is especially well illustrated by the responses obtained on case 91 (chart II, D, E and F). Fourteen responses only, on cases of hypertension are recorded, the small number being due to the fact that I rarely run a test on an individual with an

mm or over. Such cases tend to respond excessively to the test and the danger of cerebral hemorrhage from hypertension during the test must be constantly borne in mind. Details of a few of these cases will be found in a discussion of chart IV.

DISCUSSION OF CHARTS

Chart I Responses A, B and C (Case 117) A lawyer, 55 years old, first seen in 1925 (A), weight 202½ lbs, height 5 ft 8¼ in at that time, muscles flabby and pendulous abdomen. There was definite clinical evidence of myocardial insufficiency, but with no organic valvular lesion in the heart. The response to the cardiorespiratory test (A) is characteristic of a flabby heart muscle, a long delay occurring before return of the sounds to the ear after each expiration and a drop in the third step as well as in the base line, with an increase in pulse rate. After removal of diseased tonsils by Dr Lynch, and gradually increasing exercise, with a loss of 10 lbs in weight, he had improved symptomatically by 1928, when test (B) was made. While this shows an improvement in the response to the cardiorespiratory test, it is still below normal for a man of his physique. For the past three years he has engaged regularly in golf with progressive improvement physically, his muscles becoming firm with a loss in weight of 14 lbs, while his response (C) to the cardiorespiratory test is normal.

Responses D, E and F (Case 118) A business executive 61 years of age, weight 164½ lbs, height 5 ft. 7 in, has been under my constant observation since 1912. He had acute dilata-

tion in 1916 which was relieved by one month's rest in bed. Efforts since that time have been devoted to toning up the heart muscle, with the result of gradual improvement in subjective symptoms. In 1924 he still had definite signs of cardiac weakness and his response (D) to the cardiorespiratory test was poor with increase of pulse rate after test. In 1927 there was considerable improvement in clinical symptoms, while the response (E) was better. His vital capacity had increased but weakness of the heart muscle is shown by the drop in systolic blood pressure after the third expiration. At present, there is no clinical evidence of

lack of cardiac compensation, he is actively engaged in business and his response (F) to the cardiorespiratory test is normal

Responses G and H (Case 119)

Manager of numerous outdoor amusement concessions, 55 years old, weight 194 lbs , height 5 ft 9¾ in, first examined in Feb , 1929 At this time on account of dyspnea and cough and other evidence of dilatation, he was kept in bed for one month Response (G) to cardiorespiratory test made at initial examination, is very poor with a fall in step 3 and a falling base line At present there is no clinical evidence of cardiac decompensation, while re-

CHART I Showing improvement in responses to the cardiorespiratory test after compensation has taken place C, F, H, and I are normal responses (see text)

sponse (H) to the cardiorespiratory test is normal

Responses I and J (Case 120) An executive 62 years old, weight 185 lbs ; height 5 ft 8½ in, with clinical evidence of cardiac decompensation following an attack of influenza, gave only a moderate response (I) to the cardiorespiratory test in 1926 After toning up the heart muscle with regular exercise in the form of golf three times a week there was no clinical evidence of cardiac weakness, and his response (J) to the cardiorespiratory test was normal in 1927 He has continued in good health up to the present time

Chart II Responses A, B, and C (Case 92) An executive 61 years old, weight 160¾ lbs , height 5 ft 8½ in, seen first by me, Nov 26, 1928, with an enormously enlarged heart, transverse cardiac dullness measuring 20 cm , extra systoles every third or fourth beat, systolic murmur at apex not transmitted Enlargement of the liver and slight dyspnea on mounting stairs were the only evidences of an impaired heart muscle, but the response (A) to the cardiorespiratory test with a falling base line gave proof of considerable impairment of the heart muscle Clinical improvement was prompt and in 1930 the systolic mur-

* Before Test. ♦ After Test ~ Cubic Inches of air blown through Spirometer.

CHART II Showing varying responses to the cardiorespiratory test Responses B, C, E, H, and I are normal F and J are only fair responses (see text)

mur present at the apex in 1928, had disappeared, the transverse cardiac dullness was 16 cm instead of 20 cm, and the response (B) to the cardiorespiratory test was a high normal one. An examination made in Feb., 1931, showed the heart fully compensated and the response (C) to the cardiorespiratory test was still hyperactive on account of a tendency to hypertension.

Responses D, E, F, and G, H, I represent the type which is often obtained in normal individuals of the obese class, leading sedentary lives, and often showing no symptoms of cardiac decompensation.

Responses D, E, and F (Case 91)

An attorney 42 years of age, has been under my observation since 1918, but had never shown any evidence of cardiac weakness until Jan., 1927. He was obese, weighing 262 lbs., height 5 ft 10½ in. At this time he began to have extra systoles on slight exertion, which were present after test (D). This response is normal in the first two steps but the drop after third step suggested some myocardial weakness. Gradually increasing exercises under a competent physical instructor, with regulation of his diet resulted in a loss of 30 lbs by Dec 5, 1927. At this time there were no extra systoles, physically he was much improved and the response (E) to the cardiorespiratory test was normal. In 1928 he continued his exercise and his weight varied from 232 to 241 lbs. For the past two years he has given up exercise and his weight has gradually increased to 270 lbs. His response (F) to the cardiorespiratory test is low normal.

Responses G, H, and I (Case 90)

A capitalist 42 years old, weight 167 lbs., height 5 ft 10¾ in., has been under irregular observation since 1915. At college he rowed on the crew but he had taken no regular exercise in recent years. He had "flu" in Dec., 1926. On June 10, 1927 he consulted me for attacks of vertigo, intermittent pulse, and occasional dyspnea. Examination of the heart showed the apex beat 2 cm outside the nipple line, the transverse cardiac dullness was 17 cm., with an occasional, soft systolic blow audible at the apex but not transmitted. The response (G) to the cardiorespiratory test showed the heart muscle responding normally in steps 1 and 2, but falling in step 3. No medication was given, but he was instructed to play golf daily, increasing gradually the number of holes played. On June 24, 1927, two weeks later, he reported free from symptoms. No murmur was audible, heart hypertrophied and response (H) to cardiorespiratory test was normal. One hesitates to report such improvement in cardiac function in so short a space of time as two weeks, but the frequency with which I have seen this unexpected occurrence in patients taking regular exercise, who formerly, were accustomed to sedentary habits, justifies me. If one accepts Starling's teaching, as aforementioned, that the cardiac muscle does not differ functionally from skeletal muscle, this statement is less incredible. The patient reported for examination on March 4, 1931, stating that he had suffered no further recurrence of cardiac symptoms. His response (I) to the cardiorespiratory test was normal, and physi-

cal examination denoted a normal heart

Response J (Case 89) A manager of a retail furniture store, 50 years of age, weight 151¾ lbs, height 5 ft 6 in, leading a very sedentary life, consulted me Feb 2, 1926, complaining of forcible cardiac pulsations at frequent intervals. No dyspnea or other symptoms of cardiac decompensation. The transverse cardiac dullness was 14 cm. There was slight roughening of first sound, but no murmurs. No evidence of cardiac pathology could be detected. Response (J) to cardiorespiratory test is feeble and below normal, but is presented as an example of the type of

response often obtained in an individual leading a sedentary life. Such a patient continues to present a like response until exercise is enforced. I classify this type as a "lazy heart", and the usual response is probably lacking in clinical significance other than from a prophylactic, or life insurance standpoint. This patient is now in excellent health, still works hard and takes no exercise.

Chart III These curves represent three cases which have progressed downward clinically, and two fatal cases.

Responses A and B (Case 93) A physician 61 years old, weight 147 lbs,

CHART III Showing responses to the cardiorespiratory test on patients who have retrograded clinically. G and H died from coronary thrombosis (see text)

height 5 ft 9 in, has been under my observation since 1919, when signs of a failing heart muscle were detected and he was advised to curtail his activities. In 1920 he developed pulmonary tuberculosis and moved to Texas for two years, returning cured of tuberculosis and with an increase in weight of 25 lbs, but with clinical evidence of a failing heart muscle, which ultimately incapacitated him so that he was compelled to retire from the practice of medicine. Electrocardiographic tracings made by Dr. Herrmann in various positions established a diagnosis of an adherent pericardium and chronic myocardial insufficiency. Response (A) in Nov., 1925, was taken while he was still attempting to practice medicine, showing a complete failure after the third step, with the appearance of a systolic murmur at the apex and a severe cough after the cardiorespiratory test. In a few months, decompensation was marked and he consented to remain in bed for two months, which was followed by gradual compensation. A cardiorespiratory test made Feb. 4, 1926, when his heart had clinically compensated gave a response of only 15 mm (no 93b in protocol) and the appearance of a systolic blow at the apex which had not been present before the test and which was followed by severe coughing and some dyspnea, demonstrated that compensation was not complete. His heart has compensated fairly well at present and he is able to get out, but slight exertion causes dyspnea and his response (B) to the cardiorespiratory test is still far below normal, while there has been a progressive diminution in his vital capacity.

Responses C and D (Case 123) An

executive 66 years old, weight 150 lbs, height 5 ft 6¼ in responded (C) normally to the cardiorespiratory test in 1925 during a routine physical examination, at which time no evidence of any abnormality of the cardiovascular system could be detected. In Sept., 1926, he had acute dilatation of the heart with auricular fibrillation, following influenza, which compensated sufficiently for him to resume his business activities. Cardiorespiratory test (D) made May 5, 1927, showed that the heart had not fully compensated and would not maintain its efficiency under strain. He was advised to curtail his activities, which he refused to do, and since then he has had three attacks of acute dilatation.

Responses E and F (Case 122) An executive 66 years old, weight 232 lbs, height 5 ft 11 in, has been under observation since 1915, when he showed signs of beginning failure of the myocardium from obesity. Nine holes of golf daily, on a level course, so toned up his heart muscle that he was free from any signs or symptoms of myocardial insufficiency, and a cardiorespiratory test (E) in July, 1927, gave proof that his heart could withstand strain satisfactorily. During the following winter he took a trip to Nassau where he ate and drank excessively, taking no exercise and gaining 12 lbs in five weeks. On his way home, in New York, he contracted a mild afebrile respiratory infection, confining him to bed for only two days, but followed by a cough. Upon reaching New Orleans he noticed that he lacked energy and was slightly dyspneic on mounting stairs. Examination April 2, 1928, revealed an irregular, rapid heart, no

murmurs, but extra systoles and pulsus alternans, while an electrocardiographic tracing made by Dr. Rosen disclosed auricular fibrillation, ventricular extra systoles and evidence of myocardial disease. Cardiorespiratory test (F) at this time showed a poor response with a great reduction in vital capacity since the former test.

Response G (Case 91) A realtor 58 years old; weight 155 lbs; height 5 ft 7½ in, consulted me Jan. 20, 1928, for an oppressed feeling in the chest while walking fast, associated with a peculiar tingling sensation in left arm and left hand. There was no actual pain. He had noticed the symptoms for the past two months whenever he walked fast, and he stated that when he stopped the sensation would pass off promptly. There was no enlargement of the heart and no murmurs were audible until he walked briskly up and down the examination room 20 times, when a soft systolic murmur became audible at the apex. The response (G) to the cardiorespiratory test suggested myocardial weakness and he was advised to go to Clifton Springs for treatment of his heart. Unknown to me he consulted a confidante of mine, not telling him of my advice, and the latter, not hearing a murmur, told him that his heart was normal. Three months later he had an attack of coronary thrombosis while walking on the street, followed by dilatation and hypostatic pneumonia, from which he died April 27, 1928. The response to the cardiorespiratory test and the increase in pulse rate, as well as the appearance of a systolic murmur at the apex after the test gave definite evidence of myocardial weakness.

Response H (Case 95). An executive 49 years old; weight 203 lbs; height 5 ft. 11½ in, a mild diabetic, had been under observation since 1915 and repeated examinations of his cardiovascular system had never shown any abnormality until Nov 30, 1927, when he complained of a dull, aching pain in the cardiac region, not constant, but coming on usually after walking. The heart was not enlarged, there were no murmurs audible before the cardiorespiratory test (H) was run, which gave a poor response, with appearance after the test, of extra systoles and a soft systolic murmur at the apex. He was advised to go to bed and rest his heart, but instead, he went to Atlanta to attend a football game, where he had a severe attack resembling angina pectoris. In spite of rest and withdrawal from business activities, he continued to have anginal attacks and he died from coronary thrombosis Jan 27, 1930.

Chart IV. This chart is presented to show a tendency to overaction in blood pressure responses in cases of hypertension when the cardiac musculature is compensated.

Responses A, B, and C (Cases 96, 97, and 98) These all died from cerebral hemorrhage in two and one-half years, one and three-quarter years, and five months, respectively, after the tests were made. The poor response (C) of a man 53 years of age, with arteriosclerosis and a history of previous hypertension, denoted a failing heart muscle which coincided with his clinical picture. After compensation of his heart there was a return of hypertension, death following from cerebral hemorrhage.

Responses D and E (Case 99) A practicing physician 51 years of age, a case of hypertension secondary to chronic pyelonephritis, had a compensated heart in 1926 (D), symptoms of beginning loss of compensation in 1928

blood pressure of 180 mm results in a systolic blood pressure of 250 mm the danger of carrying out the test on cases of hypertension with initial blood pressure of 180 mm or over, is at once manifest and is to be discouraged

* Before Test. * After Test. * Cubic inches of air blown through Spirometer # Died

CHART IV Showing responses to the cardiorespiratory test on cases with hypertension with tendency to hyperactivity A and B are normal responses Both died from cerebral hemorrhage C is a poor response showing weakened heart muscle After heart had compensated patient died from cerebral hemorrhage G, I, and J are hyperactive responses (see text)

(E), which disappeared on curtailment of activities At present he is free from any symptoms of lack of compensation, while response (no 99c in protocol) denotes that he has full compensation F, G, H, I, and J are well except for hypertension

When one realizes that a rise of 70 mm in blood pressure over an initial

Chart V This demonstrates variable responses obtained on the same individual with varying amounts of air expired at varying pressures

Responses A, B, C, and D An executive 56 years old, obese, weighing 211 lbs, unless instructed to breathe in full lung capacity, invariably presented a poor response at first test followed

of its simplicity, is applicable to routine clinical needs in evaluating cardiac cases

2 A protocol of 125 cases on whom 160 modified cardiorespiratory tests were performed, is presented

3 A poor response was obtained in 35 per cent, a fair response in 25 per cent, and a normal response in 40 per cent of the tests

4 The response to the test corresponded to the clinical evidence of the functional capacity of the heart

5 Charts of curves plotted from responses obtained in a number of cases observed over several years, are presented, showing graphically the improvement or decline in response to the cardiorespiratory test, correspond-

ing with the clinical picture of the case

6 A failure of the systolic blood pressure to respond in an increase of at least 20 mm denotes a weakened heart muscle, while a fall in the curve of the base line denotes a serious dilatation of the heart. The pulse rate, before and after the test has clinical significance

7 The cardiorespiratory test, when properly applied, is a valuable aid in the diagnosis and study of chronic myocardial insufficiency

8 The test should be used with caution on cases of marked cardiac dilatation, on cases with a history of angina pectoris, and on cases of hypertension

Auricular Paroxysmal Tachycardia Caused by Digitalis

Report of a Case*†

BY ARTHUR F HEYL, B S., M D, *New Rochelle, N Y*

WHILE a patient, a man fifty years of age, suffering from congestive heart failure and hypertension, was being digitalized,* he returned to the clinic complaining of attacks of very rapid heart action. He stated that they were abrupt in onset and varied in duration from a few minutes to twelve or more hours. Some of these attacks were observed later in the clinic and thought to be auricular paroxysmal tachycardia. This was confirmed seven weeks after their onset (see EKG no 148, plate I, compare original EKG no 123, plate I). Since these attacks were assumed to be spontaneous an attempt was made to prevent them by more complete digitalization, following the suggestion made by Levine and Blatner.¹ The attacks, however, became more frequent with this treatment and since a review of his history indicated that he had not been troubled by palpitation of this type before he first received digitalis, the possibility was evident that the digitalis might be the cause of his at-

tacks. He was then hospitalized for study to prove or disprove this theory.

HISTORY AND PHYSICAL EXAMINATION OF THE PATIENT ON ADMISSION TO THE CLINIC

The patient, a white male, fifty years of age, hospital clinic number 8739, was seen first on August 1, 1929. His chief complaint, primarily of an asthmatic nature, was shortness of breath during the night and early morning, or with effort. This began about a year previously, following an attack of acute bronchitis.

His past history was essentially negative, except for chronic bronchitis of fifteen years duration and pneumonia at the ages of thirty-seven and forty-five years. He also had a severe attack of "grippe" during the winter of 1928-29.

His family history was irrelevant.

Physical Examination The patient was a well-nourished, tall, erect male. A most striking over-development was noticed in his full, barrel-shaped chest, with sunken supraclavicular and suprasternal fossae. There was no visible or palpable enlargement of the thyroid gland. The more important physical findings were an emphysematous chest full of sibilant and musical râles and noticeable precordial and left axillary line bulging. There was slight dullness at both bases. Heart sounds both at the base and apex were distant and ill-defined. At the lower left sternocostal angle "apex sounds" were best heard of natural quality. No murmurs could be heard. The apex and pulse rates were equal at 110 and 120, depending upon the position of the patient, reclining or erect, respectively. The blood pressure was systolic,

**Lederlé tablets and Davies, Rose and Company pills of the powdered leaf were the only preparations used with this patient

PLATE I EKG no 123, initial tracing before administration of digitalis showing left ventricular strain according to Barnes and Whitten⁷ No 148, rate 180 per minute, one of many recurrent attacks of auricular paroxysmal tachycardia after digitalization, on a maintenance dose of 0.1 gm a day

PLATE II EKG no 24, leads II and III show rare premature auricular contractions Note respiratory effect on S-wave Made ten days after discontinuing digitalis

170 mm, and diastolic, 130 mm of Hg. There was moderate edema of the ankles.

On August 24, 1929, radiographic examination of the chest at 77-inch focal distance revealed an aortic type heart with left ventricular enlargement, right interlobar pleural thickening, emphysema and bronchiectasis (plate XIII).

On Jan 16, 1930, his blood chemistry was normal, as were also his blood count and urine analysis. His blood Wassermann was negative.

A diagnosis was made of (1) Chronic heart disease associated with hypertension (pneumonia, chronic bronchitis, emphysema, bronchiectasis, asthma), (2) Greatly enlarged heart, (3) Regular sinus rhythm, occasional premature contractions, sinus tachycardia, (4) Early congestive heart failure.

Although indicating that his attacks occurred only when he was receiving digitalis (EKG no 183, plate III) the evidence during this hospitalization was not convincing, because he came to the wards after weeks of such medication and no control period free from the drug and attacks of tachycardia had prevailed. He was discharged without medication for the purpose of studying the condition further.

Tachycardia did not occur for three months until the patient on his own responsibility, because of dyspnea, took two grams of digitalis in ten days (0.2 gm a day). This resulted in an attack of tachycardia which lasted intermittently for four days.

AURICULAR PAROXYSMAL TACHYCARDIA INDUCED BY DIGITALIS THREE TIMES UNDER CONTROLLED CONDITIONS

After two more months without digitalis, in which period he had no attacks, he was again admitted to the hospital, this time in marked congestive failure. Following a rest of four days

in bed without improvement, digitalis was administered. It relieved him of failure but it also induced auricular paroxysmal tachycardia. Two subsequent observations with rest periods of seven days intervening, during which time digitalis was withheld, yielded additional proof that digitalis was the exciting cause of his attacks.

Period One (control EKG no 243, plate IX) When 1.3 grams of digitalis had been given in twenty hours, the patient complained of palpitation and an auricular paroxysmal tachycardia was revealed (no 247, plate IX). Digitalization was continued to the full calculated dose of 2.9 grams in three days and then discontinued because of a 2:1 block, with a rapid ventricular rate. The abnormal auricular rate continued (no 248, plate IX). There were no other toxic symptoms. Three days later, transient "paroxysmal" attacks occurred as the result of ventricular response to each auricular impulse (no 250, plate IX). Subsequently, the patient's usual sinus tachycardia prevailed, rate of 100 to 110 per minute (no 251, plate IX and no 252, plate X).

Period Two An interval of seven days elapsed without the administration of digitalis. After the patient had received 0.9 gram in twelve hours, he was awakened by tachycardia two and one-half hours following the third dose of 0.3 gram. This occurred at night and no tracing was obtained. Due to an additional and final dose of 0.3 gram four hours later, a 2:1 block with an auricular rate of 220 per minute resulted (nos 254 and 255, plate X). In the next four days, transient periods occurred, however, when the auricular

tachycardia was attended by a 1:1 rhythm alternating with block (EKG nos 256 and 261, plate X). Thereafter, for three days a "normal" rate and rhythm were constant (nos 262, 263 and 266, plate X)

Period Three Another week having intervened since the administration of digitalis, 0.9 gm was given within ten hours. Three hours after two-thirds of this amount had been taken, he had a regular sinus rhythm, with a "normal" rate (no 267, plate XI). Three and three-quarters hours after the final third (0.3 gm), the patient complained of tachycardia (no 268, plate XI). Block again followed for two days (nos 269, 270, 271 and 273, plate XI) and on the second and third days after digitalis had been discontinued, short periods of palpitation (1:1 rhythm) were again observed by the patient and internes but no electrocardiograms were taken. A "normal" rate with regular sinus rhythm subsequently prevailed (nos 274, 275, not reproduced; and 276, plate XI, recorded on succeeding days)

ADDITIONAL OBSERVATIONS

In an attempt to obtain more information relative to the origin of this patient's paroxysmal attacks and the relation to them of digitalis, additional observations and tracings were concurrently made. The effect of vagus stimulation by compression and eye-ball pressure, of exercise, of forced coughing; of holding a deep inspiration; all before and after the administration of digitalis, and the effects of amyl-nitrite inhalation, when no digitalis had been given, were studied.

Vagus Stimulation At this time,

no digitalis having been administered for forty-six days, right vagus compression, left vagus compression, right then left eye-ball pressure, all failed to alter materially the control electrocardiogram (no 293, plate XII)

During digitalis administration, vagus stimulation gave results which varied apparently with the dosage. Right vagus compression produced cardiac standstill for 3.6 seconds and slowing subsequently to a rate of 40 and 50 per minute, after the patient had received 1.2 gms of digitalis in divided doses during a period of twenty-five hours. The P-waves were sharpened and the T-waves deepened (no 190, plate V)

Following an increase in the daily dose of digitalis, vagus pressure failed to produce cardiac standstill. Sharpened P-waves, lengthened P-R intervals and a 2:1 block did result (no 193, plate VII)

With still another increase in the daily dose, the only result of left vagus compression was expressed by sharpened P-waves. Right vagus compression at first almost completely obliterated the P-waves and reduced the P-R interval from 0.20 to 0.12 second (nodal rhythm; dislocation of pacemaker). The T-waves were not affected as before (no 198, plate VIII). Space does not permit reproduction of the electrocardiogram but in this same tracing right and left eye-ball pressure separately gave the same results as right vagus (neck) compression.

At another time, two days after 1.2 grams of digitalis had been given in 18 hours, a run of auricular paroxysmal tachycardia was interrupted by right

PLATE VII Note the gradual transition in the last strip from ectopic to normal rhythm following vagus release

PLATE VIII

vagus pressure and resulted in 5:1, 3:1, 2:1 block (no 256, plate X)

The only effect of exercise after digitalis had been withheld for forty-six days was to increase the rate from 100 to 110 per minute. After digitalis had been administered, exercise resulted in tall, sharply pointed, ectopic P-waves (no. 157, plate II) like those appearing in his first recorded auricular

previously having been administered (no 267, plate XI). This effect also was observed when no digitalis had been given.

Holding a deep inspiration induced the ectopic P-waves, following the administration of digitalis (no 193, plate VII). When digitalis had been withheld for many days, this could not be duplicated.

PLATE-IX

PLATE IX EKG no 208, control after 1 month without digitalis No 247, rate 150 per minute

paroxysmal tachycardia (no 148, plate I). On another occasion, the effort of sitting up in bed transformed an auricular paroxysmal tachycardia, with a 2:1 a-v block, auricular rate of 180 per minute, to the same type of tachycardia with auricular and ventricular rates of 150 per minute. Reclining again resulted in the original block (no 183, plate III). These variations were immediately repeated and recorded three times with the same result.

The act of coughing produced the characteristic ectopic P-waves, digitalis

The only effects of amyl-nitrite inhalations six days after digitalis had been discontinued were an increase in the rate from 100 to 120 per minute and slight elevation and sharpening of the P-waves (no 277, plate XII).

SPONTANEOUS PREMATURE CONTRACTIONS

Spontaneous auricular premature contractions were recorded in only two of the forty-five tracings from this patient made during more than one year's observation. In the first in-

stance they occurred during digitalis administration (no 157, lead II, plate II) Nine months later, when no digitalis had been given for ten days, such premature contractions of spontaneous occurrence were recorded (no 24, leads II and III, plate II)

Spontaneous ventricular contractions also were rare (no 191, lead I, plate VI, no 247, lead II, plate IX)

COMMENTS

A thorough search of relevant work published since 1912 failed to reveal an instance of auricular paroxysmal tachycardia that was definitely proved to be due to digitalis

Bastedo² has reported a case of paroxysmal (auricular) tachycardia which he considered as produced by digitalis, but the origin of this disturbed cardiac mechanism is not accurately demonstrated since the tracings are polygrams

Howard³ presents one case and cites eleven others from the literature of double, auricular and ventricular, tachycardia due to digitalis He published only one electrocardiogram from his patient in which he found co-existing auricular and ventricular tachycardia with rates of 195 and 160 respectively The P-waves, as he states, are inverted and therefore "this represents an auricular tachycardia originating in an ectopic focus in the auricle", but the repetition of such production was not obtained because of the patient's death It is not possible to state with certainty that the digitalis was the cause

Luten⁴ reported four patients with normal cardiac mechanisms in whom temporary auricular tachycardia devel-

oped with atrioventricular dissociation after receiving large amounts of digitalis No mention is made of their being paroxysmal in type, having their origin in ectopic foci Reporting an electrocardiogram of his Case 3, he expressed the belief that the rhythm originated in the auricle "Auricular waves, however, cannot be clearly distinguished, either in this paroxysm or in that part of the record which immediately precedes it"

With the exception of Howard's case none of the eleven others which he reported, including Luten's, apparently conform to the accepted definition of paroxysmal tachycardia, having its origin in an ectopic auricular focus (Lewis⁵), and in none of them do repeated cause and effect observations make it possible to state with certainty that the digitalis induced the attacks

While in our case a tracing was not obtained showing the actual onset of a usual attack, it was observed clinically to be abrupt and furthermore, the ectopic origin of the P-waves is clearly evident

A midday control tracing (no 191, lead II, plate VI), taken by the technician, does show the gradual development of the ectopic P-waves and a progressive shortening of the T-P interval with an increasing rate This no doubt is the manner in which the paroxysmal attacks originate in this patient and from which the 2:1 block at a higher stage of digitalization results Further, in the last six complexes of no 193, plate VII, following the release of right vagal pressure, is shown the gradual relinquishment of such an ectopic rhythm corresponding

PLATE-X

PLATE X EKG no 254, auricular rate 220 per minute No 255, auricular rate 180 per minute

PLATE-XI-

PLATE XI EKG no 267, three hours after administration of total of 0.6 gm digitalis No 268, three hours and forty-five minutes after final total administration of 0.9 gm digitalis

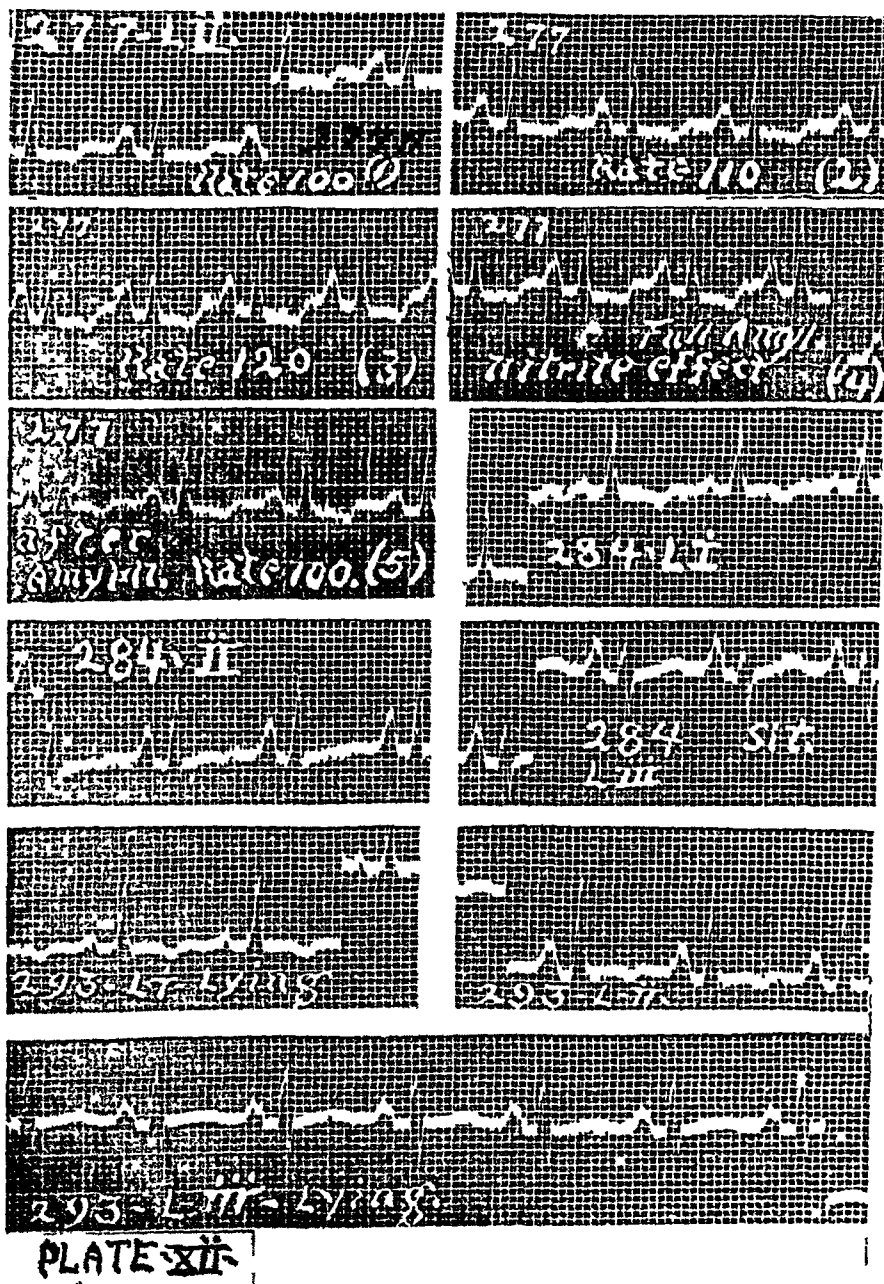

PLATE XII EKG no 284, control 26 days after discontinuing digitalis. Note postural and respiratory effect on deviation of electrical axis as compared with No 293 twenty days later

to an end phase of his auricular paroxysmal tachycardia

In electrocardiogram no 183, plate III, while the auricular paroxysmal tachycardia is present with a 2:1 block, the onset of 1:1 rhythm, the release of block, is nicely shown, occasioned by sitting up in bed. The interruption of such ventricular response, re-establishment of a 2:1 block, is also shown. Such transitions likewise are seen in no. 250, plate IX, without previous effort

SUMMARY AND CONCLUSIONS

1 Presented with an adult male, past middle age, having hypertension and congestive heart-failure, it was observed more than nine times that the digitalis, which gave him relief from his symptoms (dyspnea, cough, passive congestion, edema) concomitantly induced auricular paroxysmal tachycardia followed by a 2:1 block, in which the abnormal auricular mechanism prevailed

2 These abnormal rates and rhythms occurred only as the result of digitalis administration

3 The writer was unable to find any reference in the literature to such a mechanism due to digitalis so conclusively proven

4 Various methods, such as effort, deeply held inspirations, forced coughing and amyl-nitrite inhalations were utilized in an attempt to induce the attacks, both in the presence and in the absence of digitalis administration. When no digitalis was being administered they were consistently unsuccessful. Ectopic P-waves like those occurring with his attacks were, however, obtained, but in only one instance, by

forced coughing, when he was free from the drug

5 Various attempts were made to ascertain the effects of vagus stimulation. While he was free from digitalis, external vagus stimulation did not produce any change in the cardiac rate or rhythm nor any electrocardiographic variations. Neither did digitalis alone, even in full dosage, slow the rate as would have been true had it acted directly on the vagus. But the heart at different times, affected by different amounts of digitalis, was rendered susceptible to external vagus stimulation in effects varying from complete cardiac standstill to 5:1, 3:1, 2:1 block, with auricular slowing; to nodal rhythm and no slowing, or to ectopic P-waves and no slowing, depending on the size of the dose. These vagus responses, occurring only in the heart affected by digitalis, correspond to the method of Weil⁶ for determining the onset of toxic digitalis effects

6. Spontaneous premature contractions were exceedingly rare, either of auricular or ventricular origin, in the presence or absence of digitalis administration

7. No toxic symptoms due to digitalis ever occurred, even with full calculated dosage, except the abnormal mechanisms previously mentioned.

8 The practical significance of these observations is, as others have noted, that graphic methods are especially valuable for diagnosis in patients with sinus tachycardia, particularly in those who need and are receiving digitalis. In this instance even mild doses repeatedly resulted in auricular paroxysmal tachycardia, with or without a

Plate XIII

2:1 block with a rapid ventricular rate, which without electrocardiographic control, might naturally have led to the futile use of more digitalis and increased toxicity in an effort either to slow the ventricular rate or to prevent

the often recurring "clinical" auricular paroxysmal tachycardia.

I am indebted to Dr Harry Gold of New York for his helpful criticism and suggestions in the preparation of this report

Hospital Diets

“A ROUTINE hospital diet should no more be a mysterious affair than a prescription for the pharmacist. If its existence is at all justified, it should be based on the same rational principles that govern all other forms of therapy. A routine diet should have a purpose, a plan, and an objective; it should be based on the laws of nutrition, it should contemplate specific needs in the patient, it should have its indications and its contraindications. Properly employed, the routine hospital diet becomes a convenience to the physician, to the administrative staff, and to the patient.”—(From *Clinical Dietetics*, by HARRY GAUSS, M S, M D, F A C P, C V Mosby Company)

Medical and Surgical Problems Associated With Coronary Sclerosis*†

BY ARLIE R. BARNES, M D , F A C P , *Rochester, Minn*

TODAY, beyond doubt, heart disease is the "captain of the men of death." Coronary sclerosis accounts for a large proportion of deaths from heart disease. This might not be so depressing if death from coronary sclerosis came after a long life, but too often the condition claims its victim when he is in his prime and when elsewhere in his body there is no evidence of serious deterioration. There is a distinct need for a review of the common aspects of this disorder, to bring into sharper view its clinical manifestations, and to call attention to the bearing the newer knowledge has on the solution of the many problems which coronary sclerosis presents.

Additions have been made to knowledge of the normal coronary circulation and its pathologic changes. Spalteholz, Gross, Whitten and Campbell have greatly enlarged knowledge of the normal coronary circulation. The distribution of the branches of the right coronary artery to the basal and posterior portion of the left ventricle, described by these writers, has not received the attention it deserves and the result has been failure to appreci-

ate the frequency with which that portion of the left ventricle may be the site of infarction. The work of Whitten disclosed striking variation in the structure of the coronary arteries, depending on whether they are distributed to the right or the left ventricle. Branches of either the right or the left coronary artery, going to the left ventricle, leave the main trunks at right angles, penetrate the myocardium, and when they reach the endocardial surface turn at right angles, ending in a mass of fine arterioles. This has the effect of fixing the main trunks at the points of origin of the penetrating branches. When arteriosclerosis occurs, with resultant lengthening of the vessel, it leads to more or less angulation of the main branches at the points of fixation. This, together with the disproportionate degree of arteriosclerosis that occurs about the mouths of these penetrating branches makes for greater narrowing at these points, and increases the liability to thrombosis of the main branches.

On the other hand, the smaller branches of the right coronary artery, going to the right ventricle, spread out in the same plane as the main divisions from which they arise, and these small branches anastomose freely. This may be one explanation of the almost total

*Submitted for publication, May 7, 1931.

†From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

absence of acute infarction in the right ventricle

Gross is of the opinion that with advancing years there is increasing impoverishment of the circulation through the right coronary artery as compared with that through the left. Whitten's studies did not support that view, for he wrote "The portion of the right coronary artery which supplies the left ventricle keeps pace in its vascular development with the left coronary artery in successive decades." Certainly if myocardial infarction can be considered as an index of the inadequacy of the coronary circulation, the overwhelming frequency of its occurrence in the left ventricle indicates failure of the circulation to the left ventricle with advancing years rather than failure of the circulation of the right ventricle.

Comparative anatomy shows that the presence of coronary arteries is associated with the development of a cortical myocardium.²⁵ In the lower animals the blood circulates in the intratriabecular spaces, through the whole thickness of the cardiac walls. Higher in the animal scale, in reptiles, the inner trabecular part of the myocardium retains a thebesian, sinusoidal circulation while there is a definite coronary circulation to the cortical portion of the wall. There is free communication between these two systems of circulation. In the rabbit "the thebesian, intertrabecular circulation is much reduced, but it retains its connections with the coronary capillary system, and persists as an integral part of the adult myocardial blood supply."²⁵ It is not surprising, therefore, that Wearn²⁶ and his co-workers²⁷ have been able to demon-

strate in man communication of the coronary circulation with the chambers of the ventricles, either by way of the thebesian vessels or by means of coronary capillaries communicating directly with the ventricular chambers. Cases of bilateral occlusion of the ostia of the coronary arteries have been reported. The occlusions presumably had occurred gradually, and probably had existed for some time prior to the attack. It is apparent that in such cases the circulation to the heart had to take place by way of the thebesian veins, through their connection with the coronary circulation.

Besides the thebesian circulation, there is a variable degree of pre-capillary anastomosis of the coronary arteries. The coronary arteries are no longer considered to be strictly end arteries. The degree of anastomosis appears to have individual variation, and on this account it may be assumed that some persons are inherently endowed with a coronary circulation which is little able to cope with acute closure of a coronary vessel. The degree of anastomosis tends to increase with advancing age, and that may be one reason why fewer persons more than seventy years of age die of acute coronary occlusion than those of an earlier age. The rate of obliteration of coronary vessels also plays an important part in the extent to which anastomotic channels develop. The studies of Oberhelman and LeCount may be interpreted to mean that in those normal hearts in which there is a negligible amount of anastomosis of the coronary vessels and in which the arteries are essentially end arteries, sudden occlusion of an artery is likely to result in sudden death. In hearts

which are fairly normal, and which possess rich collateral circulation, sudden occlusion of a vessel may be well tolerated, may lead to infarction and subsequently to healing by fibrous replacement. In hearts with slow development of sclerotic narrowing, abundant coronary anastomosis is likely to occur and it is in this group that sudden coronary occlusion is best tolerated. As Benson remarked, "It must be concluded, then, that arteriosclerotic narrowing of the coronary arteries as related to thrombosis of these vessels, is not an unmitigated evil in that it gradually prepares them for the catastrophe that is to come."

The pain observed following acute occlusion of a coronary vessel certainly appears to have a definite pathologic basis. The major difference between this pain and that which is unassociated with coronary occlusion is probably one of degree only. Atheroma of the coronary arteries is the common lesion found in cases of coronary sclerosis, and the pain is considered to be the result of anoxemia¹⁴ due to a blood supply "suddenly insufficient for the needs of the heart muscle for the moment."¹⁰ In certain cases of angina pectoris, sufficient changes in the coronary vessels to account for inadequate blood supply are lacking, and a paroxysmal vasomotor spasm has been postulated to explain these cases. The demonstration by Anrep and Segall that there is vasomotor control of the coronary circulation in the dog might be regarded as supporting the conception of such a mechanism of production of pain. However, the explanation of anginal pain on the basis of paroxysmal vasomotor spasm is at present devoid of

any reliable clinical or experimental proof.

Angina pectoris is sometimes observed in cases of pernicious anemia,³³ hyperthyroidism,¹² and paroxysmal tachycardia.⁶ There are evidences that in many of these cases the coronary vessels are not the seat of notable disease. It seems highly probable that the factor productive of pain, common to all these mechanisms, is a coronary circulation that is inadequate in the amount of oxygen furnished to the cardiac muscle. It is important to note that angina pectoris arising from any of these conditions is usually overcome by correction of the underlying disturbance. Consequently, the prognosis of angina pectoris, when it arises from these causes, is much better than when the condition has its origin in coronary sclerosis.

Coronary sclerosis affects the main branches of the coronary vessels, diminishing in degree as the smaller branches are approached. Even in cases of malignant hypertension, the arterioles are less affected than are the arterioles elsewhere in the body.¹⁵ The intima is eccentrically thickened, and atheroma is the common lesion. This may lead to gradual occlusion of a large vessel, and subsequent canalization of the occluded portion occurs rather commonly. Thrombi frequently form at the site of ulcerating and calcareous atheromatous plaques, leading to sudden occlusion of the vessel at that point. Syphilis at present is regarded as having little significance in the production of disease of the coronary vessels, except at their origin, where syphilitic aortitis frequently leads to occlusion of the ostia.

The myocardium, in cases of coronary sclerosis, may not exhibit changes, or it may be involved in varying degrees of myocardial necrosis and replacement with fibrous tissue. Diffuse myofibrosis, interspersed with fairly normal muscle fibers, is found in the region supplied by a severely diseased vessel, and probably results from gradual occlusion of the vessel. This process is considered to be due to chronic infarction, and its degree will be influenced by the amount of injury that exists in the vessel, and by the extent of the development of accessory channels of circulation. Hypertrophy of the heart is present in the majority of cases of coronary sclerosis, but this is probably the result of the frequent association of the condition with hypertension. It is not uncommon, however, to encounter hearts of normal size with severe degrees of coronary sclerosis.

Coronary sclerosis and peripheral arteriosclerosis are not necessarily concomitant phenomena. Essentially normal coronary arteries are seen at times in cases of marked peripheral arteriosclerosis. Conversely, the coronary vessels may be markedly sclerosed, while there may be little injury to the peripheral vessels.

Knowledge of the etiologic factors in coronary sclerosis is inadequate. It seems fair to consider that coronary sclerosis is a part of the aging process, and the aphorism that "a man is as old as his arteries" might be changed to state that "a man is frequently as old as his coronary arteries." Coronary sclerosis and coronary occlusion are much more likely to develop in men than in women. A person whose family history contains records of severe

vascular disease is predisposed to the development of coronary sclerosis. The ordinary acute infections appear to be unimportant; in fact one is struck by the frequency with which patients who have coronary disease give histories of being remarkably free from episodes of acute infection. Syphilis is a factor in coronary disease in those cases in which syphilitic aortitis produces atresia of the coronary orifices. It is difficult to evaluate the part focal infection plays in the production of disease of the coronary vessels. One gets the impression that patients who have coronary sclerosis have, if anything, less focal infection than the average patient, whereas patients with much focal infection do not seem unduly prone to the development of coronary sclerosis. In my experience, removal of foci of infection in cases of coronary sclerosis has not produced any evident effect on the course of the disease. The occurrence of hypertension accelerates the development of coronary sclerosis, as does diabetes mellitus. Persons with certain constitutional characteristics tend to be victims of coronary sclerosis. Such persons are often powerfully built, and are possessed of great energy and endurance. A life that is strenuous either mentally or physically is frequently the lot of patients who die from disease of the coronary vessels.

The most characteristic symptom of coronary sclerosis is angina pectoris. Heberden's original description¹³ of angina pectoris is exact, and little has been added to it since. Heberden wrote as follows:

"They who are afflicted with it are seized while they are walking (more especially if it be up-hill, and soon after eating) with

a painful and most disagreeable sensation in the breast, which seems as if it would extinguish life if it were to increase or continue, but the moment they stand still all this uneasiness vanishes

"In all other respects the patients are, at the beginning of the disorder perfectly well, and in particular have no shortness of breath, from which it is totally different. The pain is sometimes situated in the upper part, sometimes in the middle, sometimes at the bottom of the os sterni and often more inclined to the left than to the right side. It likewise extends very frequently from the breast to the middle of the arm. The pulse is, at least sometimes, not disturbed by the pain, as I have had opportunities of observing by feeling the pulse during the paroxysm. Males are more liable to this disease, especially such as have passed their fiftieth year. After it has continued for a year or more, it will not cease as instantaneously upon standing still, and it will come on not only when persons are walking, but when they are lying down, especially if they lie on the left side, and oblige them to rise out of their beds. In some inveterate cases it has been brought on by the motion of a horse or carriage and even by swallowing, coughing, going to stool, speaking, or any disturbance of mind.

"Such is the usual appearance of this disease, but some varieties may be met with. Some have been seized while they were standing still or sitting, also upon first waking out of sleep, and the pain sometimes reaches down the right arm as well as the left and even down to the hands, but this is uncommon, in a very few persons the arm has at the same time been numbed and swelled. In one or two persons the pain lasted some hours or even days, but this has happened when the complaint has been of long standing and thoroughly rooted in the constitution, once only, the very first attack continued the whole night."

It is often necessary to make a diagnosis of angina pectoris when cardiac abnormalities are not revealed on general examination or by electrocardio-

graphic or roentgenologic study. It is as if one were called on to identify a man by the shadow he casts or by his silhouette and to do that one must be familiar with every curve, shadow and gesture of the man. To identify a case of angina pectoris without any assistance from any methods of examination demands a most complete mental picture of the syndrome.

I should like to call attention to Heberden's localization of the pain in the sternal region, inasmuch as pains in the lateral portion of the thorax frequently are construed incorrectly as symptoms of disease of the coronary arteries. If pain occurs in the region of the sternum following exertion the presumption is that the case is one of coronary disease, and only the best evidence is sufficient to attribute the pain to any other cause. On the other hand, when the pain is in the left lateral portion of the thoracic wall, the evidence is against a diagnosis of coronary disease and that diagnosis should be made only after the most careful analysis of the symptoms. If the pain is in the left lateral portion of the thoracic wall one must first think of myalgia, intercostal neuritis, herpes zoster, renal colic, diaphragmatic hernia, adherent pericardium, referred pains caused by arthritis of the thoracic portion of the spinal column, lesions of the spinal cord and even the indefinite pains of neurasthenia often associated with cardiac neurosis.

The most characteristic feature of the pain of coronary disease is that it is precipitated by any factor which increases cardiac work and is fairly promptly relieved when the increased demand on the heart ceases. The on-

set of pain following walking is much more convincing in making a diagnosis than it is when it follows the use of the arms, and stooping or bending. The latter exercises bring into play the thoracic muscle, or the spinal column, and lack the value in differential diagnosis of walking, in which many muscles are used. The relation of the pain to changes of weather often identifies it as of rheumatic origin. The details of the manner in which the patient gets relief may be of diagnostic value. One patient, who had his pain in the precordium at night, and who obtained relief by taking warm drinks or by sitting with his back to the fire, proved to have an area of anesthesia in the left lateral portion of the thorax, at the site of his pain, due to advanced hypertrophic arthritis of the thoracic portion of the spinal column.

The brief duration of the pain of coronary disease should be noted. When a patient is subject to repeated attacks of thoracic pain, which last from a half hour to several hours, one must hesitate to make a diagnosis of angina pectoris. A single episode, or at most two episodes, of prolonged precordial pain, may be shown to be associated with one or more attacks of coronary occlusion, but a series of such seizures cannot be so interpreted.

Coronary sclerosis may manifest itself by other symptoms than angina pectoris. Paroxysmal nocturnal dyspnea, with or without pulmonary edema, may be the chief manifestation of coronary sclerosis. However, this symptom is most frequently observed in those cases in which coronary sclerosis is associated with essential hypertension.

Willius and Brown found that in twenty-six per cent of patients with coronary sclerosis, the disease was manifested by progressive myocardial failure, unassociated with seizures of pain. Scott, likewise, has emphasized the fact that there is a considerable group of patients without anginal pain or hypertension, who run the characteristic course of heart failure which proves, at necropsy, to have its basis in coronary sclerosis. As he stated, these patients often are considered to be suffering from chronic myocarditis, which is an erroneous term. This term is doubly unfortunate, indicating that the pathologic process in the heart is inflammatory and implying that "chronic infection elsewhere in the body is responsible for the myocardial damage,"²² for neither of which assumptions is there substantiating clinical or experimental evidence.

And finally, all students of this subject are familiar with the fact that coronary sclerosis, even with coronary occlusion and chronic myocardial infarction, is found in persons who have had no clinical signs of heart disease to the time of their death. This group was designated occult coronary disease by Willius, and comprised forty per cent of his cases.

On general examination there may be no objective evidence of heart disease, and as previously mentioned the diagnosis must rest solely on the interpretation of the patient's symptoms. In a considerable proportion of cases a variable degree of cardiac hypertrophy is present, and this usually occurs with associated hypertension. Significant arrhythmia is relatively uncommon. Pulmonary congestion, and

eventually hepatic enlargement, with edema of the legs, occurs in cases which exhibit the syndrome of chronic heart failure

The roentgenogram of the heart will confirm the presence of hypertrophy when it exists and often reveals calcareous deposits in the aorta. It may also give evidence of widening of the aortic arch, due to torsion and slight ectasia, a finding that is often interpreted erroneously as evidence of aortic aneurysm. Needless to say roentgenographic evidence has only an indirect bearing on the diagnosis of coronary sclerosis.

The greatest confusion exists in the matter of the relation of the electrocardiographic data to the diagnosis of coronary disease. There is a tendency among clinicians to exclude the diagnosis of coronary disease in the absence of significant electrocardiographic changes, and yet Willius³¹ has shown that significant T-wave negativity or abnormalities of the QRS complexes were absent in 63.3 per cent of cases of angina pectoris. As far as my experience goes, coronary sclerosis can affect the electrocardiogram in only three ways. First, a characteristic electrocardiographic change usually is observed in the first two or three weeks following acute coronary occlusion, which in many instances is pathognomonic.^{2, 5, 21} This is followed by inversion of the T-wave and a peculiar RS-T contour described first by Pardee and designated the coronary T-wave by him. The term coronary T-wave is freely and loosely used, and yet this is the only instance that warrants such a designation. The T-wave negativity may require six months to two years

to disappear after infarction. In the second place, coronary sclerosis may affect the function of the auriculoventricular bundle and may lead to varying degrees of heart block. Finally, it may impair conduction in either division of the bundle branches, leading to varying degrees of bundle-branch block with or without inversion of the T-waves. There is yet another condition in which inversion of the T-wave is observed in coronary sclerosis, namely, when that condition is associated with strain, predominantly of one ventricle, usually due to hypertension. Our studies⁴ indicate that this change is primarily due to unilateral ventricular strain rather than to coronary sclerosis. Pardee²⁰ recently described a large Q-wave in lead III of the electrocardiogram, unassociated with right axis deviation, which he considers to be an indication of narrowing of a coronary branch or branches. In sixty-three per cent of the cases studied, this abnormality was not attended by significant changes in the T-wave. If further critical studies confirm this observation, it will become an important electrocardiographic sign indicative of coronary sclerosis.

Finally, it must be emphasized again that by no means is it necessary to have abnormalities of the electrocardiogram before making a diagnosis of coronary sclerosis.

Acute coronary occlusion and myocardial infarction are much more common events than is ordinarily supposed. Studies which Ball and I made of the incidence of myocardial infarction among 1,000 consecutive patients who came to necropsy showed that there was gross myocardial infarction in 49

per cent of hearts. In the group of patients in that series who were more than forty years of age, the incidence is 68 per cent. Contrary to present ideas, occlusion of the branches of the right coronary artery that go to the left ventricle was found to be common. It is no longer justifiable to speak of the anterior descending branch of the left coronary artery as "the artery of coronary occlusion". As a logical sequence to these observations we found infarction of the posterior basal portion of the left ventricle to be practically as common as infarction in the apical and anterior portion of the left ventricle. The study further emphasized that myocardial infarction is almost entirely confined to the left ventricle.

One cannot enter into a detailed description of the pathologic changes which follow acute coronary occlusion, but certain features are worthy of comment. Death may occur following acute coronary occlusion so quickly that an anatomic infarct may not have time to form. If one wishes to demonstrate the coronary thrombus in these cases "scissors are unsafe instruments for opening the coronary arteries" because of the danger of dislodging the clot. In cases in which infarction has existed a little longer, its presence may be indicated on gross examination only by a region in which muscle softening has taken place and not by changes in the surface coloring of the myocardium. Rupture of the heart occurs in the first three weeks, as a rule. It is the result of the rapid necrosis of the heart muscle which takes place at that time and not ordinarily the result of cardiac aneurysm, which occurs later, due to thinning of the muscle wall, associated

with more or less complete replacement of the muscle with fibrous tissue. Many infarcts will be overlooked unless the pathologist incises the left ventricle, parallel with and at a distance of 0.5 to 1 cm. from the posterior interventricular septum. When the muscle beneath a depression in the surface of the left ventricle is sectioned, an underlying chronic infarction often is revealed. Mural thrombi are formed frequently when the infarction extends through to the endocardium, or in certain cases of prolonged and severe myocardial failure. The danger of a portion of this thrombus becoming dislodged and leading to serious or fatal embolism exists chiefly during the first three weeks after the thrombus is formed. Pericarditis occurs in from twelve to fifteen per cent of cases of myocardial infarction, hence the physical signs of this condition may be anticipated in relatively few cases of coronary occlusion. Two or more infarcts of varying ages may be found in the left ventricle, and this often explains clinical facts and varying electrocardiographic changes that otherwise might prove puzzling.

Acute coronary occlusion frequently afflicts patients not previously subject to symptoms of heart disease. Conner and Holt observed that sixty-two per cent of patients with coronary thrombosis did not give histories of antecedent circulatory symptoms. Although our experience, and that of Levine, has been that careful questioning usually will disclose a history of angina pectoris or of other symptoms of heart disease, yet the fact remains that acute coronary occlusion is frequently the first intimation of a cardiac disorder.

The onset of the attack may be signalized by a severe, prolonged attack of substernal or epigastric pain, occasionally by an attack of severe suffocation, and in rare instances it may occur without pain and with little, if any, dyspnea. The pain is distinguished from the ordinary attack of angina pectoris chiefly by its duration. Often large doses of morphine fail to relieve the patient of pain.

The appearance of the patient following acute coronary occlusion is characteristic in the majority of instances. There is an anxious, grayish facies, and the patient is bathed with perspiration. Dyspnea is usually present. Frequently the patient is nauseated, and severe retching and vomiting are seen in some cases. Fever of one to three degrees develops on the second day and persists for several days. The blood pressure usually falls, sometimes to an alarming degree.

On general examination the apical tones are usually somewhat indistinct, and gallop rhythm is often observed. Pulsus alternans is present occasionally. A friction rub can be heard over the precordium in about twelve to fifteen per cent of cases during the first week. Auricular flutter, auricular fibrillation, or tachycardia of auricular or ventricular origin, is sometimes present. At times the infarct extends high enough in the septum to involve the bundle of His, producing complete auriculoventricular block. Willius⁸⁰ reported two cases in which Stokes-Adams syndrome resulted from such involvement of the auriculoventricular bundle.

Leukocytes number from 10,000 to 20,000 during the first week. A sec-

ondary rise in the leukocyte count may indicate impending myocardial rupture or an additional acute infarction.

The electrocardiographic tracing is characteristically modified, depending on the site of infarction.⁵ When infarction occurs in the anterior portion of the left ventricle and apex, in the region usually supplied by the left coronary artery, the earliest electrocardiographic evidence of the fact is a change of level and contour of the S-T or R-T segment in leads I and II and depression of the S-T interval in lead III. The R-T segment in leads I and II, but especially in lead I, is elevated above the iso-electric line. The segment is likely to be convex, dome-shaped, or sloping downward toward the T-wave. Diphasic T-waves, or T-waves of a monophasic type, are the rule in the earliest stages. It is important to note that leads I and III act conversely, so that elevation of the R-T interval in lead I is opposed by depression of the S-T wave in lead III. The changes in lead II are usually seen to be similar to those in lead I in cases of infarction in the anterior portion of the left ventricle. Two or three weeks after acute coronary occlusion the monophasic or diphasic type of T-wave is replaced by frank inversion. The T-waves are likely to be deep, abrupt, or sharply peaked. It is noteworthy that as the T-wave becomes inverted in lead I, the T-wave in lead III remains upright, and becomes exaggerated and sharply peaked. Of particular significance in this later stage is the rounded contour of the R-T interval in lead I or in leads I and II, preceding inversion of the T-wave. At this stage, the R-T interval is approach-

ing or has reached the iso-electric level.

With infarction in the posterior portion of the left ventricle, alone or combined with apical infarction, precisely the opposite set of conditions is seen. In this case, in the early stages, the R-T segment is elevated in leads II and III and depressed in lead I. The same convex, dome-shaped, or sloping R-T segment preceding the T-wave is apparent in leads II and III. In the later stages, the R-T segment in leads II and III tends to return to and eventually reaches the iso-electric level, and the depressed S-T interval in lead I disappears. In this stage, inversion of the T-wave in leads II and III, with a rounded contour of the preceding S-T segment, is observed, whereas the T-wave in lead I is upright, and becomes exaggerated and more sharply peaked. It must be emphasized that if the patient survives for a period varying from six months to two years, evidence of inversion of the T-wave tends completely to disappear and the electrocardiogram returns to normal.

After the first few days, and for a period of possibly three weeks, portions of the mural thrombus formed over the site of infarction may be dislodged, producing embolism in the systemic arteries. If these emboli lodge in cerebral vessels they are likely to cause death. Death may also occur from rupture of the myocardium due to necrosis extending rapidly through the ventricular wall. A considerable number of patients die from congestive heart failure.

Approximately half of the patients survive acute occlusion of a coronary vessel. Some of these continue to have attacks of dyspnea or anginal pain.

Many have subsequent attacks of coronary occlusion to which they succumb. A considerable proportion of those who survive are free of trouble in six to eighteen months, and are capable of assuming their usual activities with little, if any, reminder that they have been victims of such a vicious cardiac insult.

The problem of coronary sclerosis and occlusion concerns the surgeon in three main ways. First it is obviously important to recognize or to be able to exclude this condition in cases in which operation is to be performed for any cause. Searching interrogation of the patient for a history of anginal seizures, of prolonged attacks of substernal pain or of prolonged seizures of suffocation must always be carried out, especially if the patient is a man of more than forty years of age. Inversion of the T-waves, not associated with cardiovascular conditions that are capable of producing unilateral ventricular strain nor with increased width of the QRS interval of the electrocardiogram often give a clue to the existence of previous coronary occlusion. The peculiar character of these T-waves has been well described by Pardee.¹⁹ Inverted T-waves in leads II and III are commonly indicative of myocardial infarction, particularly if digitalis has not been given. Obviously, an antecedent history of angina pectoris calls for more lively suspicion that infarction has occurred previously.

If it is recognized that acute myocardial infarction has recently occurred, and the patient is in need of a surgical operation, it is advisable to postpone operation, if possible for three months, for the studies of White

have shown that healing is fairly complete in that length of time. Of course, operation may be undertaken then only if examination demonstrates that cardiac compensation is satisfactory. Under certain urgent conditions it has been found possible successfully to perform a major operation on patients whose acute coronary occlusion occurred as recently as two weeks prior to the operation. However, this is permissible only in emergencies, or in cases in which attacks have been mild, have been accompanied by a minimal amount of shock, and in which there is no evidence of heart failure after the attacks.

The surgeon, and the internist as well, are vitally interested in distinguishing acute coronary occlusion from pathologic conditions in the abdomen, particularly cholelithiasis, perforating peptic ulcer, intestinal obstruction, and acute pancreatitis. This difficulty comes about because acute coronary occlusion may register its pain in the abdomen, whereas, the abdominal lesions enumerated may produce pain in the lower part of the thorax with radiation of pain to the shoulders and even at times to the arms. As Tuohy remarked, collateral and associated evidence is often of more importance than direct evidence and symptoms in arriving at the correct diagnosis. Although the differential diagnosis cannot always be made, yet vivid appreciation that coronary thrombosis can simulate the abdominal conditions named will avoid many embarrassing surgical experiences.

First and foremost, one must be ever mindful of the menace of coronary occlusion among patients who are more

than forty years of age, and particularly if the patient is a male. An antecedent history of angina pectoris or paroxysmal nocturnal dyspnea speaks strongly for the possibility of acute epigastric pain having its basis in acute coronary obstruction. The absence of such a history does not allow one to exclude from consideration acute coronary occlusion, however. The presence of essential hypertension, or its preexistence, predisposes to an attack of coronary occlusion.

The most important step in distinguishing acute conditions in the abdomen from acute coronary obstruction, is the careful taking of the anamnesis. This is particularly true if patients have cholelithiasis or peptic ulcer, in such cases a painstaking review of the history usually will suffice to establish the presence of these conditions. If one remembers that cardiac arrhythmia, muffled apical heart tones, gallop rhythm, friction rub and particularly a rapid drop in blood pressure are symptoms of cardiac insult, the differential diagnosis usually can be made. Wilkus and Fitzpatrick found that the gallbladder was diseased in twenty-four per cent of cases of coronary sclerosis. When disease of the gallbladder or peptic ulcer exists with acute coronary obstruction, it may be difficult or impossible to arrive at a differential diagnosis.

It can now be said that the electrocardiogram assumes the greatest importance in the differential diagnosis of these conditions. Abnormalities of the electrocardiogram which have been enumerated, appear as early as four hours after acute myocardial infarction, and may retain a highly characteristic

appearance for two to three weeks or longer. It is imperative, therefore, for the internist and surgeon to familiarize themselves with these highly diagnostic changes.

In distinguishing acute coronary obstruction from acute pancreatitis and intestinal obstruction, the electrocardiogram may be of diagnostic value if twenty-four or more hours have elapsed after the onset of the attack. The fecal vomiting, "ladder pattern" seen on inspection of the abdomen, and abdominal rigidity will establish the diagnosis of intestinal obstruction as a rule. As between acute pancreatitis and coronary disease the diagnosis must rest on the occurrence of local tenderness and rigidity in pancreatitis, the history relative to coronary disease, the physical signs of cardiac injury, and possibly on the electrocardiographic changes.

Finally, the surgeon is interested in

the problem of the surgical treatment of angina pectoris. Here a plea for conservatism must be made. First of all, operations undertaken on patients with angina pectoris are done at considerable risk. Second, if the surgeon is successful in alleviating pain there is no reliable evidence to indicate that he has modified the serious pathologic process that is the basis for the pain. It is even debatable how much one is justified in depriving the patient of the signal which will warn him that his heart is in distress. At present we are inclined to reserve attempts at surgical relief to patients who fail to obtain reasonable help from the combined use of xanthine derivatives and adherence to a strict regimen. If this treatment fails, the surgical procedure of choice is the conservative method, consisting of paravertebral injection with alcohol of the upper five thoracic nerves.

Pulmonary Infections by the Friedländer's Bacillus (*Bacillus Mucosus Capsulatus*)*†

BY FRANK FREMMEL, M D., KARL J. HENRICHSEN, M D., AND
HENRY C. SWEANY, M D., *Chicago, Ill*

SINCE Weichselbaum's¹ work in 1886, it has been known that the micro-organism described by Friedländer² in 1882-3, can cause pulmonary disease *suu genenis* Friedländer's conception, however, that it was the cause of all pneumonias, was disproved by Frankel just prior to Weichselbaum's report. On the other hand, Frankel considered the micro-organism only a secondary invader and not the primary cause of any pneumonia—a conception that was also partially erroneous, and one that divided medical opinion for many years.

Sisson and Thompson³ emphasized this and pointed out that Osler as late as 1912 expressed Frankel's view in his text book on medicine. Gradually, however, reports have accumulated to show the true status of the parasite, viz that from one to eight per cent of pneumonias are caused by it. The work of Weichselbaum has, therefore, been confirmed by a large number of authors, the most important of whom are Étienne,⁴ 1895, Comba,⁵ 1896, Smith,⁶ 1897, Thierloix,⁷ 1897, Howard,⁸ 1898, Bero,⁹ 1899, Moiseyeff,¹⁰ 1900, Brinckerhoff and Thompson,¹¹

1901, Kakawa,¹² 1904; Stuhlern,¹³ 1904, Apelt,¹⁴ 1908; Brissaud,¹⁵ 1912; Gouget and Moreau¹⁶ 1912; Mosny and Pruvost,¹⁷ 1913, and Zander,¹⁸ 1928.

Some of the authors tend to dissociate these infections from other lung infections and to establish them as separate disease entities. Especially is this true of the chronic form.

The unusual features of these infections are a definite and specific bacteriology, a peculiar clinical course with sudden death and extremely high mortality, and a characteristic gross and microscopic pathology.

The clinical course of the disease is not always regular, but most authors speak of a sudden onset, usually without a chill, no herpes labialis, death coming suddenly between two to five days, usually before the third day. Occasionally, however, the process may resemble closely a lobar pneumonia except that it usually terminates more suddenly. The physical findings are given by Weill and associates¹⁹ as those of engorgement rather than hepatization, even in the advanced process. There are signs of some dullness, with suppression of breath sounds, and an absence of subcrepitant râles. This is perhaps due to the large numbers of

*Received for publication, May 4, 1931.

†From the Research Laboratories of the Municipal Tuberculosis Sanitarium, Chicago.

encapsulated bacilli that fill the alveoli and finer bronchi with a sticky mucoid material, preventing the passage of air.

The mortality figures differ slightly, but with the exception of Zander¹⁸ who reported an epidemic of the disease where the mortality was thirty-five per cent, the mortality figures are high. Netter, quoted by Étienne,⁴ Brissaud,¹⁵ Mosny and Pruvost,¹⁷ Gouget and Moreau,¹⁰ Kakawa,¹² and others, stated that the disease is nearly always fatal. Lord,²⁰ in 1915, said that no authentic case had ever recovered. There are sporadic reports, however, of patients of varying grades of chronicity. Recently Belk,²¹ Westermarck,²² Collins and Kornblum²³ and others have reported such cases.

Zander's series, mentioned above, seems to be unusual in that it assumed epidemic proportions, yet had a much lower mortality than is reported for the sporadic cases, and perhaps is more truly representative because it is a series nearly as large as all others reported, put together. It shows the effect of such an infection on an average group of people (soldiers in a prison camp), while Friedländer's infection is usually reported as occurring, most frequently in people of low vitality, quite commonly in alcoholics around fifty years of age. It is possible that many recoveries are never reported or even suspected as such infections.

The roentgenologic findings are rather meager. Weill thought that it differs from pneumonia in having a less tendency to show triangles, and Collins and Kornblum,²³ in being less dense, more scattered and nearer the periphery of the lung in location.

The bacteriology is relatively con-

stant. The causal organism is a large round ended, gram negative, heavily encapsulated bacillus. It has since been placed in a distinct group of encapsulated micro-organisms. Although it resembles the organisms found in rhinoscleroma and ozena, and also other members of the group, it is quite different in pathogenicity. Culturally, it resembles the colon-aerogenes group, but differs in its heavy capsules and in a few incidental reactions. Some authors suggest an origin from this group, but such ideas have not met with general acceptance. Notwithstanding the fact that strains of these micro-organisms have a general similarity, there are slight variations that may very well account for some of the clinical and pathological differences.

The pathological changes are the most distinctive and will, when taken together with other findings, differentiate this condition from other lung affections. Moiseyeff,¹⁰ Kakawa¹² and Brissaud¹⁵ emphasized its individuality. While Sisson and Thompson³ stated that no feature is pathognomic, yet when all are taken together it is quite easy to make a diagnosis. The most important pathologic findings are the pseudolobar consolidation due to a dense confluence of bronchopneumonic foci (rarely true lobar), the absence of a red stage of hepatization, the presence of a mucoid exudate on the cut surface giving it a glazed appearance, the scarcity and irregularity of red cells and fibrin within the alveoli, and the presence of a moderate number of monocytes containing large numbers of the encapsulated bacilli. Hyperemia and thrombosis of the alveolar vessels lead up to a necrosis and ab-

DISCUSSION

One of the striking features of this case was the rapid evolution and apparent utter hopelessness of treatment. This is in harmony with the majority of reports. Although the cases reported by Zander¹⁸ and the scattering ones in which the disease becomes chronic, will be encouragement for further effort, there appears to be some unknown toxic

substance that overwhelms the patient. This assumption is well supported because only the left lower lobe was involved, yet a profound agranulocytosis of the blood developed, with collapse and death within twenty-six hours from the initial chill. It seems reasonable to suppose that a soluble toxin may be responsible for the sudden prostration. If such should be found, there

FIG 1 Antero-posterior sagittal section through the middle of the left lung. Huge pneumonic focus in the middle of the lower lobe, extending out to the pleura except at the extreme margins. While this is almost lobar in extent, it is essentially the same type of lesion that begins as a smaller focus.

is no disease in which there is greater need for an antiserum so far as the individual patient is concerned

Perhaps the greatest need in these infections is promptness in diagnosis. This dictum is true of any disease but, here, from a prognostic standpoint it is especially valuable. The diagnosis

can be made only by finding the encapsulated bacilli inside of monocytes in the sputum, the cellular content of which is predominantly monocytic. This, with vague physical signs of pulmonary engorgement, accompanied by a cyanosis and physical state out of proportion to the physical and x-ray

FIG 2 High power photomicrograph of the pneumonic process, showing a monocyte (a) containing encapsulated bacilli, alveolar wall (b) with necrosis and rupture at 'c' and 'd' X1090

findings, establishes the diagnosis. Subsequently, the x-ray shadows become more pronounced (but never like a lobar pneumonia). Bacilli may be found in the blood. It must be differentiated from croupous, broncho-, and (rarely) lobar pneumonia. Although our acute case was a lobar pneumonia, few authors report typical lobar types. Most of them (Brissaud,¹⁵ Kakawa,¹² Moiseyeff,¹⁰ Étienne,⁴ and others) consider the most common type a "pseudo-lobar" or irregularly confluent bronchopneumonia with a less common true bronchopneumonia. Only a few (Brissaud and Kakawa) make mention of a true lobar pneumonia. The differentiation from these conditions must be based on the sputum findings together with the vague and almost negligible physical signs (râles in particular) in an extremely ill patient. The explanation of the paucity of râles is no doubt found in the extreme viscosity of the exudate. This, in turn, is due to the mucoid capsules of the bacilli.

As to the chronic types, they must be differentiated from pulmonary abscesses and gangrene, unresolved pneumonias, particularly that of influenza, and pulmonary tuberculosis. From the common abscess it may be differentiated by the characteristic sputum with the bacilli and the relatively slight odor. From influenza by the sputum with the characteristic bacilli, and from tuberculosis on the bacteriological findings and, according to Kornblum,²³ by the thin walls of the cavities as shown on the x-ray. Our chronic case was indistinguishable, however, from some types of ulcerative pulmonary tuberculosis.

SUMMARY

An extremely acute type of Friedlander's bacillus infection is reported, the patient living only twenty-six hours from onset to death. The clinical findings corresponded to those usually reported for the disease. The pathological findings were those of an uncommon lobar pneumonia instead of a confluent bronchopneumonia, or a "pseudo" lobar pneumonia. The disease began by a rapid growth of the encapsulated micro-organisms in the alveoli and smaller bronchi, causing an exudate rich in edema fluid containing scattering monocytes, irregularly placed fibrin, with an occasional hemorrhage into the alveoli. This aspect has only a gray to yellow-gray appearance grossly, and accounts for the infrequent appearance of the red stage of hepatization. Death occurred before the other stages could develop. Ordinarily the evolution of the lesion from the "red" stage is characterized by an infiltration of polymorphs along the alveolar walls, forming in crescents along the plugs composed of bacilli, monocytes, and varying amounts of fibrin. Later an invasion of the alveolar wall results in a huge dilatation of the alveolar capillaries, followed by thrombosis, necrosis, and abscess formation. The last two processes correspond to the stage of resolution of pneumococcus pneumonia. The dilatation of the alveolar capillaries, with an occasional rupture into the alveoli, give to the lesions a mottled dark red appearance that is occasionally present.

If the patient survives this stage, a gradual change to a chronic form ensues, with a substitution of lymphocytes and plasma cells for the poly-

morphs and an invasion of the older lesions with fibroblasts, connective tissue, and a true metaplasia forming squamous or cuboidal epithelial cells over the cavity walls. When the disease is progressive, there is a continuous sequence of lesions that begins in small bronchopneumonic foci and

passes through the various stages of evolution described above, usually extending downward towards the base until death.

The bacteriologic studies included in this report have been made by Miss Asya Stadnichenko, for which we wish to express our gratitude.

The Phobia of High Blood Pressure

“**A**T present, the general public, at least in the large cities, is entirely too well acquainted for its own good with the dangers of arterial hypertension. Almost everyone knows some unfortunate who had high blood pressure and died suddenly in the street, or is now paralyzed in half his body. Or when he tells his solicitous friends that he has been discovered to have high blood pressure, they will fill in the gaps in his knowledge of the dangers of the disease. Fortunately, by now the blood pressure has been measured long enough for one to have communicative friends who have had the dreaded high blood pressure for many years and ‘never been hurt by it’. It is very common nowadays for one who has always felt well to learn as a result of an insurance or periodic examination or a visit to the doctor for some trivial complaint that he or she has high blood pressure. Then, often enough, the peace of mind of the patient is gone, symptoms make their appearance, and there start the troubles of the patient and, even more, of the family

At the outset, it is to be emphasized that *many individuals with essential hypertension not only need no treatment whatsoever, but are much better off without it*. Many persons with asymptomatic hypertension would have been more fortunate if they had never learned of their hypertension.”—(From *Hypertension and Nephritis* by ARTHUR M FISHBERG Second Edition, 1931 Lea and Febiger, Philadelphia)

Syphilis of the Lung*†

Report of a Case with Autopsy Findings

By HAROLD COMONFORT DENMAN, M D , F A C P , *Brooklyn, N Y*

FLOCKEMANN,¹ whose comprehensive review of the literature of pulmonary syphilis was published in 1898, stated that "the existence of pulmonary syphilis in the adult has not been proved to be very probable" This statement has been doubted by other writers on the subject Rossle² believed that the frequency of pulmonary lues in the adult is underestimated and reported twenty-five cases which he himself had observed Allison³ stated that "Syphilis of the lung in the adult is unquestionably rarely encountered However it is not so rare as pathologists would lead us to believe, and conversely, not nearly so common as some clinicians and roentgenologists seem to think" This uncertainty, the difficulty of diagnosis and the paucity of characteristic findings in pulmonary syphilis have prompted the report of the following case

W G , a laborer, aged 42 years, was admitted to the medical service of Kings County Hospital, November 9, 1930, because of a hemorrhage from the mouth The following history was obtained from the patient Two months before admission, he had noticed a persistent cough productive of a small amount of sputum This cough was never

excessive nor painful The sputum was in small amount, white and never blood tinged He noticed also a slight but increasing weakness during this period, which did not interfere with his usual work The hemorrhage which was the cause of his admission to the hospital, occurred suddenly, without cough, pain or unusual exertion, and was described by the patient as a gush into the mouth of blood, bright red in color and slightly frothy He was unable to state the amount Associated symptoms were lacking, there were no chills, fever, no sweats, dyspnea, palpitation or precordial pain He had a fair appetite, no nausea, no vomiting, bowels regular, not medicated He slept well, and suffered no discomfort from a nocturia, twice nightly, except the inconvenience, and although poorly nourished, had noticed no appreciable recent loss of weight

The *family history* shows that his father died of erysipelas, age not known to the patient His mother, two sisters and one brother are alive and well, no history of tuberculosis, malignancy or congenital disease is present

Previous personal history During childhood the patient had measles During adult life the only disease was acute rheumatic fever at the age of 23 years While serving in the World War he was informed that he had heart disease, but was not discharged for incapacity His habits were regular, drinking very little alcohol, no coffee, tea freely, but not to excess

Physical examination revealed a slight, small framed, poorly nourished, pale, adult male about five feet five inches tall, complaining of weakness and a recent hemorrhage from the mouth Head, eyes, nose,

*Received for publication, April 10, 1931

†From the Medical Service, Kings County Hospital, Brooklyn, N Y

and ears were negative. There were no glandular enlargements in the neck or axilla. Chest examination showed a narrow, asthenic type, with markedly diminished expansion of the entire left side. Tactile fremitus was present anteriorly, to a less extent below the third rib, than over the corresponding area on the right side. This tactile fremitus was increased in the left axilla and absent over the left base posteriorly below the fifth dorsal spine and laterally to the scapula angle. The supra- and infraclavicular fossae were deeper on the left side. There was no dilatation of the superficial veins of the chest. Percussion revealed the presence of a solid body in the third left interspace between the mid-clavicular line and the sternum. Between the mid-clavicular line and the mid-axillary line from the third to the seventh interspaces a hyperresonant note was present. Flatness was present posteriorly below the level of the fifth dorsal spine and laterally to the scapular angle. On auscultation the breath sounds were diminished anteriorly and in the axilla, and increased at the level of the third space anteriorly with occasional loud "bubbling" râles over this area, and absent over the flat base posteriorly. The voice sounds were diminished slightly anteriorly and not transmitted at the base posteriorly. There were fine crepitant râles over the left apex only after an expiratory cough, none at the base. The right side gave the physical signs of compensatory breathing.

The cardiac apex impulse was visible and palpable 8 cm from the mid-line in the fifth interspace, the rate was 100, normal sinus rhythm. There were noticeable carotid and subclavian pulsations. The left border was percussed 8.5 cm in the fifth interspace, the right border, 4 cm to the right in the fourth interspace, and the arch, 6.5 cm at the level of the second interspace. The first cardiac sound was entirely replaced at the apex and base by a harsh systolic murmur, followed by a short, ringing, greatly accentuated second sound. The radial pulses were equal and regular. The abdomen showed no localized areas of tenderness, no palpable masses and no herniae. The inguinal glands were palpable and hard. Rectal examination revealed a normal pros-

tate. The extremities were negative, and reflexes normal. The blood pressure in the right arm was 110/60, in the left, 114/70.

The possibilities in this patient were abscess of the lung, aneurysm of the aorta, tuberculosis, gumma of the lung, malignancy. Although there was a slight effusion in the left pleural cavity on admission, it was believed to be due to, rather than the cause of, the localized findings (Figure 1). Seventeen days after admission the patient showed signs of a rapidly formed, large effusion in the left pleural cavity and a roentgen picture at this time proved the presence of an effusion, which on aspiration was bloody (Figure 2).

During the patient's stay in the hospital, his main complaint was an increasing weakness, with a slight unproductive cough. Although his lesion changed, his complaint remained much the same, weakness. On admission his temperature was 100° going to normal in two days and remittent thereafter, varying between 99.6° and 102°, the average being 99.9°. The pulse rose to 120, the respirations to 34, averaging 26. After withdrawing 1,000 cc of sero-sanguineous fluid from the left pleural cavity on the seventeenth day, for an artificial pneumothorax, a thoracentesis was necessitated again on the thirty-fifth day with the withdrawal of 2,000 cc of bloody fluid, but without great relief. An increasing dyspnea and cyanosis supervened. His pulse became weak and more rapid, his right chest gave evidence of a beginning passive congestion, hemoptysis recurred with the loss of four ounces of bright red blood, and on the forty-ninth day of hospitalization, the patient expired. The laboratory reports gave normal urine, sputum negative for tubercle bacilli on fourteen occasions, blood Wassermann four plus, blood chemistry normal. The blood count and differential was white blood cells, 10,800, red blood cells, 4,200,000, polymorphonuclears, 78 per cent. In the examination of the pleural fluid cancer cells were not observed. Guinea pig inoculation was negative for tuberculosis.

A post mortem examination was performed by Dr. William W. Hala, director of the pathological laboratories of the Kings Coun-

FIG 1 (Nov 13, 1930) Absent aeration of the left lower lobe. Small effusion in the costo-phrenic space. Left chest smaller than the right. Moderate compensatory emphysema of the right lung. The left border of the heart shadow obscured by lung pathology. (Interpretation of the x-ray films was by Dr Richard A Rendich, roentgenologist at Kings County Hospital.)

FIG 2 (Dec 1, 1930) Complete absence of illumination of the left lung field, consequent to a large collection of fluid in the pleural cavity, slight displacement of the heart and mediastinal contents to the right

FIG 3 (Dec 1, 1930) Oblique view after removal of one liter of sero-sanguineous fluid, air injection for study of pleural neoplasm—latter excluded by the normal pleural contour. Sacular aneurysm of the descending aorta now distinctly visualized. (From a P A view at the same time, the patient lying on his right side, the horizontal level of the remaining fluid was noted, with the absence of neoplastic mass of the parietal pleura.)

FIG 4 (Dec 12, 1930) Further accumulation of fluid—several levels denoting small encysted collections

ty Hospital, whose report follows, only data of positive interest being recorded here

Main incision The liver extended three inches below the costal margin in the midline There were about 32 ounces of yellow

low the base of the lung, and encapsulated The amount of pus present was about 400 c c On the posterior aspect of the lung and in the midline, in the region of the fifth and sixth dorsal vertebrae, there was

FIG 5 Organizing pneumonia in syphilis A Alveolus entirely obliterated by fibroblastic tissue which is rather rich in cells of the small round and histiocytic type B Hyperplasia of interstitial tissue of the lung C A band of fibroblastic tissue bisecting an alveolus D An alveolus containing numerous large round cells, (exfoliated alveolar epithelia) The arrow points to an almost obliterated alveolus

fluid in the peritoneal cavity The pericardial sac contained 25 c c of clear fluid The left pleural cavity contained one quart of straw colored fluid

The *left lung* was adherent to the chest wall, and from the base a copious thick purulent exudate escaped, coming from an area situated above the diaphragm and be-

noted a bulging of the descending branch of the aorta Just below the bifurcation of the bronchi on the left side and postero-lateral, there was found a well circumscribed area the size of a golf ball, which contained about 10 c c of thick purulent material In apposition to the upper portion of the lower left lung was found a sacculated aneurysm

The *right lung* was heavy and of a dark gray color, the pleura was thickened and the lung substance had a "shotty" feel

Lungs, trachea, esophagus, and aorta were removed in toto

The trachea was dissected down to the

The *aorta* had the described sacculated aneurysm, together with longitudinal striations of mother of pearl color and raised plaques with marked thinning of the wall.

The *lungs* on section showed diffuse tubercles and in the upper lobes of both lungs

FIG 6 Syphilis of the lung The illustration shows productive inflammation induced by lues, practically no alveoli being preserved At 'A' is an area of replacement fibrosis The arrow points to a miliary gumma

bronchi and the left bronchus was dissected to its terminus A seeping hemorrhagic tract was noted extending from a small pinpoint perforation of the aneurysm into the substance of the posterior portion of the lower left lung The sacculated aneurysm, about the size of a lemon, was situated in the region of the fifth and sixth dorsal vertebrae

small cavitations and caseous material were observed In the lower lobes of both lungs there was carnification In the lower left lung there was an increased amount of stroma without aeration or crepitation Near the base of the left lung, about one inch below the hilus, there was a grayish, rubber like mass the size of a five cent piece The lungs presented the gray stage of hepatiza-

tion, and were firm throughout the whole middle and lower right lobes, and the upper left lobe

The heart showed a myocardium of good quality, its valves and orifices grossly normal

Microscopical Examination The heart showed focal areas of interstitial myocarditis, and chronic epicarditis. The lungs showed a chronic fibroid productive pneumonia. In some areas this was still in the active stage showing marked organization. In other areas it was characterized by definite fibrillated replacement of the lung parenchyma, areas of bronchopneumonia and areas of abscess formation. Examination likewise disclosed the presence of numerous focal collections of small round cells, invariably along the pulmonary interstitial stroma. These collections were considered pulmonary gummata. There was no evidence of tuberculosis or neoplasm. In one section there was a rather large hemorrhage, occurring not only in the parenchyma of the lung proper, but in a rather large number of the bronchioles. It was highly probable the result of the ruptured aneurysm. The spleen showed a chronic splenitis, congestion and edema. The kidneys showed congestion, edema and an early vascular nephritis, the aorta, a syphilitic aortitis.

Anatomic Findings Syphilitic aortitis, aneurysm of the descending thoracic aorta, chronic fibrinous pleurisy, empyema, encapsulated, left side, pneumonia, lobar type, gray stage, sero-fibrinous pleurisy of the right side with atelectasis of the lower right lung, atelectasis of the lower left lung, chronic passive congestion of the liver and spleen, acute nephrosis with vascular nephritis, hydropericardium, gumma of the left lung.

Syphilis of the lungs is rare and is seldom diagnosed clinically. In a search through the museums of the London Hospitals and the Royal College of Surgeons, Fowler⁴ found but twelve specimens. Two of these cases were doubtful. At the Johns Hopkins Hospital, Osler⁵ reported twelve cases out of 2,800 autopsies. Of these twelve,

only four were acquired. Among 3,000 autopsies at the Massachusetts General Hospital, Lord⁶ found only one case of acquired syphilis. Symmers,⁷ in a study of 4,800 autopsy protocols, 314 of which showed lesions of syphilis, reported twelve cases and syphilitic pleural lesions in two more (Orsten⁸). Of 110,258 admissions to Kings County Hospital between and including the years 1919 to 1925, a period of seven years, the number of syphilitic patients, diagnosed as such by a positive Wassermann reaction, the history, or physical signs, was 5,695. Not one of these was diagnosed as syphilis of the lung. Dr. Henry Monroe Moses,⁹ in a review of syphilis on his medical service at Kings County Hospital, between Dec 1, 1923, and March 1, 1926, found in a series of 2,450 patients, 191 diagnosed as having syphilis. These patients were usually in the late stages of the disease, and sought hospital treatment because of some intercurrent ailment, or because of disability due to syphilitic involvement of some organ or organs of the body. Of the 191 patients in this series, the intercurrent illness was in the lungs in fifty. There were twenty-four with pneumonia, eighteen with lobar and six with bronchopneumonia. There were twenty-six with pulmonary tuberculosis. All of these patients were acutely ill on admission. There were seven deaths among these fifty patients, with forty-three who recovered or felt well enough to demand their own release. Of the seven deaths one was diagnosed as pulmonary syphilis, but unfortunately an autopsy was not obtained.

Syphilis of the lungs occurs as the congenital form—so called white pneu-

monia—which is a diffuse fibroblastic proliferation with an interstitial infiltration of small round cells, and is seen in stillborn babies or those dying shortly after birth. It may occur also in the acquired form as a chronic interstitial pneumonitis or syphilitic phthisis. It may occur as gummata, which is the usual type, and be rather sharply defined with radiating strands into the lung tissue. In the case reported here, we have a combination of these two forms. Rossle² differentiates four types of the disease. He distinguishes (1) the cavernous syphilitic phthisis; (2) the gummatous, coarse, knotty form, (3) the coarse lobulated syphilitic scarred lung (*pulmo lobatus*), and (4), the coarse syphilitic callosity without pronounced changes of the exterior form or shape.

According to Councilman,¹⁰ the essential process in the production of a gumma in the lung is a pneumonia with fibrinous change in the alveolar walls, the whole subsequently undergoing caseation. The first step in the process is stated to be a hyaline degeneration of capillaries of the affected area. This is followed by atrophy of the alveolar walls. The alveoli become distended with large, pale, epithelial cells and fibrin, the cells also undergo hyaline degeneration, forming smooth bodies staining with eosin, and varying in size from one-half the diameter of a red blood corpuscle up to that of a large epithelial cell. The capillaries become converted into rigid tubes, and their lumina are much narrowed. Similar changes occur in the small veins and arteries. Immediately around the bronchi and arteries there is a forma-

tion of connective tissue, and here the alveolar walls show much thickening and contain many small round cells.

Gummata of the lung in elastic consistency resemble gummata found in other organs, occurring as nodules embedded in the tissues and surrounded on all sides by radiating fibrous strands. They may be single or in numbers, and may vary in size from that of a minute point as small as the smallest tubercle to the size of a hen's egg or larger, but the latter size is of rare occurrence. The central portion is firm, rubber-like, grayish white or yellowish like hard cheese. The necrotic, caseous part is analogous to that found in tubercles, but differing in its elastic, firm consistency and in its slighter tendency to liquefy. A section through a gumma in the lung tissue might have exactly the appearance of one from a large caseous encapsulated tubercle in the same situation. Buhl¹¹ was the first to call attention to the persistence of smooth muscle fibers in the pulmonary callosity in chronic pneumonitis, while Tanaka¹² and Rossle² found not infrequently smooth muscle in the lung in syphilitic processes. Demonstration of the spirochete or of the tubercle bacillus would not settle the matter, for Schmorl¹³ found spirochetes indistinguishable from *Spirochaeta pallida* in pulmonary gangrene and aspiration pneumonia, but these searches are notoriously discouraging of result.

The Wassermann reaction might afford important evidence. But as a rule the gross appearance and distribution of the lesions are found to be typical enough in each disease to allow one to

discriminate Gummata have a strong tendency to heal, so that they are commonly found as disappearing centers of caseous material in great radiating scars, at times causing strictures, deformities, or obstruction, as in a bronchus. The presence of these lesions on roentgen ray examination, in the absence of obvious tuberculosis and when other signs of syphilis exist, warrants a diagnosis of gummata, but doubtless many of those described may have been localized encapsulated tubercles, or having in mind the apparent rarity of lung syphilis, gummata may have been diagnosed as tubercles.

"Gummatous infiltrations have a tendency to occur around the hilus of the lung and in the lower lobe. Occasionally areas of lobular hepatization are observed" (Hala¹⁴). The walls of the bronchi or the large vessels at the hilum of the lung may be greatly thickened by the process, the adventitia of the vessels suffering. By pressure of gummata or stricture of scars, obstruction of a bronchus may occur with atelectasis of the lung field, or the so-called indurative bronchiectatic type of pulmonary syphilis may supervene.

"Whether pneumonic or ulcerative forms of syphilis with cavity formation really exist is uncertain" (MacCallum¹⁵). Fowler⁴ reports from the museum of Guy's Hospital a case of multiple gummata of the lungs, one of which was softening, breaking up and in the process of forming a cavity.

The confusion with tuberculosis makes this point difficult to settle (Flockemann¹), especially since syphilitics are prone to tuberculosis (twenty-six of 191 on our service at Kings

County Hospital during the years 1923 to 1925).

"In the diagnosis of pulmonary syphilis by the roentgen ray there is no characteristic picture"¹⁶ This diagnosis should be made only by the history, a positive Wassermann reaction and the result of antisyphilitic treatment (Jaches¹⁷). "In the light of our present knowledge, even a tentative diagnosis of pulmonary syphilis is not warranted until every other possible type of pulmonary disease is excluded" (Allison³).

"The history of the case, the Wassermann reaction, the bacterial findings, the distribution of the lesions and the relation to lesions elsewhere, the size, consistence and gross appearance, the tendency to heal or break down, the continued absence of tubercle bacilli in the sputum, and least of all, the histologic structure, are the things upon which a diagnosis of syphilis in the tertiary stage may be based" (Allison³).

From the complicated pathological descriptions of pulmonary syphilis it is not difficult to realize that the clinical picture of this condition is not characteristic. The symptoms simulate those of pulmonary tuberculosis, and the diagnosis of tuberculosis is usually made. MacCallum's description of the tertiary stage of syphilis and how difficult it is to differentiate it from tuberculosis, especially in the lungs, may be a good explanation for syphilis of the lung being so rare as an autopsy finding (Orsten).

There is presented here a patient having syphilis of the lungs proven by autopsy findings.

Observations on the Contour of Normal and Tuberculous Female Chests*†

By S A WEISMAN, M D, F A C P, *Minneapolis, Minn*

IN previous reports^{1, 2} various diameters of normal and tuberculous male chests were compared. They showed that the tuberculous chest was more rounded, longer, and deeper than the normal chest, and that the vital capacity was about forty per cent greater in the healthy chest. In this paper the normal and tuberculous female chests will be compared. For normals, three hundred University of Minnesota girls were examined in the Spring of 1930 at the Women's Gymnasium. For tuberculous chests the data obtained on one hundred and thirty-three tuberculous women at Glen Lake Sanatorium, Oak Terrace, Minnesota was used.²

The ages of the normal girls ranged from sixteen to twenty-four years and of the tuberculous group from sixteen to sixty years. In order to make the comparison as close as possible, the tuberculous cases were divided into two groups, fifty cases representing the ages sixteen to twenty-four and eighty-three cases representing the ages twenty-five to sixty.

THORACIC INDEX

The average thoracic index, which is the ratio of the depth of the chest

to the width, for three hundred University girls was 70.2. In comparing this average with those found by other investigators it was found that the Minnesota girls stand very high in chest development. Wilder and Pfeiffer³ in reporting measurements on one hundred students at Smith College, stated that because the girls came from all parts of the Union it represented an average for the womanhood of the United States. The average thoracic index reported by them was 72.3. This represents a more rounded and less developed type of chest than that found for the University of Minnesota women by about three per cent. The same technique and statistical methods were used as described in my previous reports.

Again in 1929, also from Smith College, Steggerda, Crane and Steele⁴ reported measurements on one hundred girls. The average thoracic index found by them was 75.2, which is 6.5 per cent deeper than that of our series. Their findings show a much deeper and more rounded form of chest.

The thoracic indexes for our series of tuberculous chests were

Group I, ages 16 to 25, 73.3,

Group II, ages 25 to 60, 72.1

After determining the probable error for the two groups and for the normals and computing the difference in terms of probable error, the findings

*From the Department of Medicine, University of Minnesota, and the Glen Lake Sanatorium, Oak Terrace, Minn.

†Received for publication, June 2, 1931.

are of some significance in comparing the two groups

In comparing the normals with the first group of tuberculous chests, both ranging from sixteen to twenty-four, the difference in terms of probable error is 4.2. This indicates definitely that the tuberculous chest is more rounded than the normal

ceptible to tuberculosis. Malone⁵ and Hall⁶ have shown by means of pantographic tracings that the better developed chest is flat and has a greater vital capacity. Muller⁷ and Hutchinson⁸ have shown that the chest of the fetus is deeper than it is wide. Scammon and Rucker⁹ have demonstrated that a baby's chest at birth is nearly round,

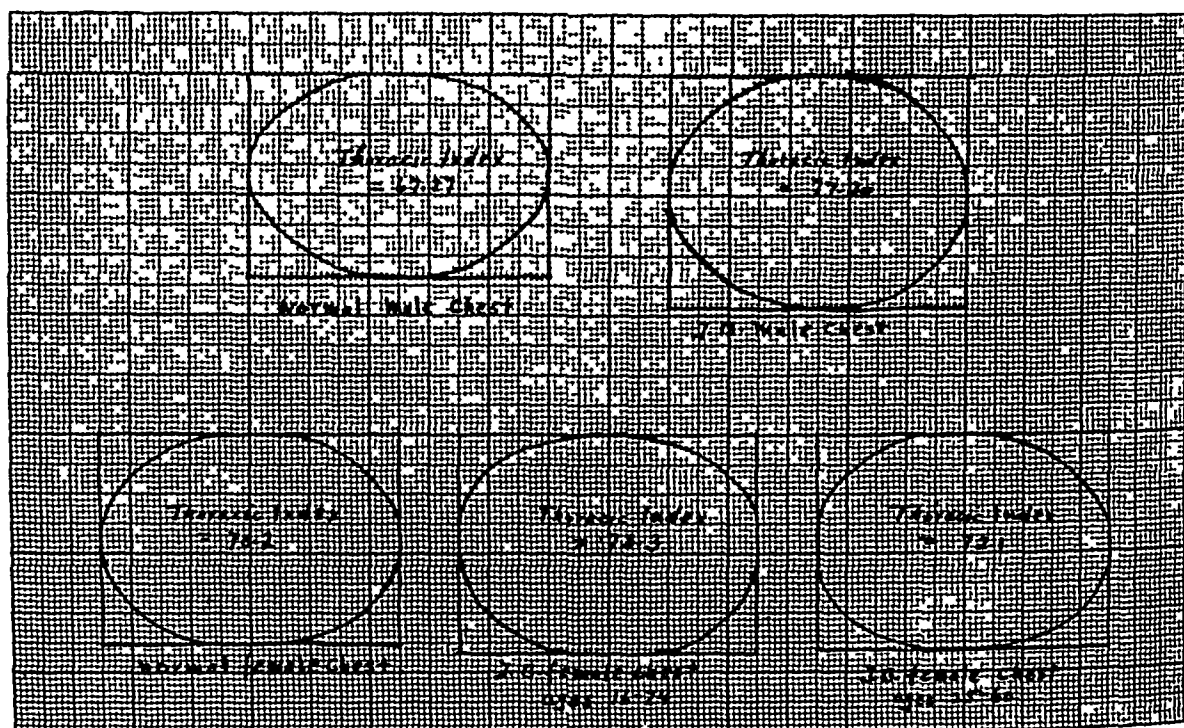

FIG 1 Diagrammatic sketches of chest diameters

In comparing group II, ranging in ages from twenty-five to sixty, with the normals, the difference in terms of probable error is probably, but not certainly, significant, namely 2.67

The above figures tend to show that the older tuberculous group have a flatter and better developed chest than the younger group. This fact emphasizes a point brought out in previous reports,^{1,2} that the deeper, rounded chest is an undeveloped one, it is the primitive chest, it has a lower vital capacity, and it is, perhaps, more sus-

ceptible to tuberculosis. Malone⁵ and Hall⁶ have shown by means of pantographic tracings that the better developed chest is flat and has a greater vital capacity. Muller⁷ and Hutchinson⁸ have shown that the chest of the fetus is deeper than it is wide. Scammon and Rucker⁹ have demonstrated that a baby's chest at birth is nearly round, that it gets deeper after the first respiration and that it is about three months or more before it reaches the thoracic index it had at birth. Zeltner¹⁰ has shown that the chest becomes more flattened up to the twentieth year, and Stewart¹¹ states that the vital capacity at about the twentieth year is the greatest. At this age the chest begins to change toward the infantile type and slowly assumes a more rounded form until development ceases at about the sixtieth year, as shown by Weisenberg.¹²

Therefore one should expect an older person to have a more rounded chest than a younger one, and an older individual with tuberculosis should surely have a more nearly round or deeper chest than a younger one afflicted with the same disease. Our findings, however, show the opposite to be true

losis, it had a better vital capacity and warded off the disease until later in life

Draper¹³ in his book, "Human Constitution," gives the measurements of twenty-eight tuberculous female chests. The thoracic index was calculated as 74.5 which is a more rounded chest

FIG 2 Cumulative number graphs of thoracic indexes in groups of women considered

The older tuberculous group have flatter and better developed chests than the younger tuberculous group. This perhaps indicates that the nearer round or the less developed the chest is in early life, the more liable is that individual to develop pulmonary tuberculosis. The flatter chest, like that found in group II, probably means that that chest was more resistant to tubercu-

than either of our groups. The difference, as with other investigators mentioned above, may have been due to the technique used. In our series the normal female chest was found to be more rounded than the male. Rodes¹⁴ showed that the female negro chest is narrower than the male. Draper, too, showed that the female white chest is narrower than that of the male. Jack-

son¹⁵ has shown that the average chest expansion and vital capacity in the female is less than it is in the male. In our series² of six hundred and five University of Minnesota male students the thoracic index was found to be 67.27.

THE SUBCOSTAL ANGLE

The subcostal angle in the normals and two tuberculous groups was measured. A definite difference between the normal and the diseased chests was found. The average for the three hundred normal girls was 75.9° and for group I of the tuberculous, 68.7°. The difference in terms of probable error is 5.46. The average for group II of the tuberculous is 71.1°. The difference in terms of probable error is 4.8. These findings, too, are in accord with those of the thoracic index, that the older tuberculous group has a better developed chest than the younger group.

AGE

The average age for the three hundred normal girls was 18.7 years, and for the tuberculous group I, 21.1 years. The range in both of these series was

between ages sixteen and twenty-four. Tuberculous group II ranged from twenty-five to sixty years. The average age was 31.7 years.

COMMENT

As was emphasized in the previous reports, perhaps it is wise to again stress the importance of measuring, as a routine, the chests of children. In this way one is more able to find those with undeveloped chests, chests that are perhaps more susceptible to tuberculosis. Proper exercises can help improve the undeveloped chest. Gotz¹⁸ working with children, and Turner's¹⁷ recent report of results on young female adults show that proper exercises increase the vital capacity of the lungs.

CONCLUSIONS

1. Female tuberculous chests are shown to be more nearly round and deeper than the normal.

2. There is a possibility that the rounder the chests the earlier in life is one apt to contract tuberculosis.

3. There is evidence that proper exercises in early life can stimulate chest development.

TABLE I

Summary of Indexes of Thoracic Measurements (Female)

Type	Thoracic Index	Subcostal Angle	Average Deviation		Probable Error		Difference in Terms of Probable Error			Age	
			Thoracic Index	Subcostal Angle	Thoracic Index	Subcostal Angle	Thoracic Index	Subcostal Angle		Range	Average
Normals	70.2	75.9°	4.46	4.48	±0.229	±0.256				16 to 24	18.7
Tuberculous*											
Group I	73.3	68.7°	3.00	10.2	±0.695	±1.33	4.2	5.46		16 to 24	21.1
Group II	72.1	71.1°	6.00	9.81	±0.675	±0.978	2.67	4.80		25 to 60	31.7

*The thoracic index of the tuberculous female chests reported in my previous paper (2) is 72.6 instead of 72.1 (Error in printing)

American Mountain Tick-Fever—Semiography and Nosology

With Remarks on Pathology and Treatment*

By NOXON TOOMEY, M D , F A C P , *Palmyra, Mo*

THE tick borne fever of the mountainous areas of western North America has on several occasions since 1850 been the subject of brief remarks and of other publications of a more comprehensive character. It cannot be said, however, that the disease has ever been adequately described. All of the early and more recent descriptions of the disease show the want of knowledge concerning its etiology, its epidemiology, and its immunological relationships. Indeed, the published observations on the American mountain tick-fever have been for the most part either fragmentary or confused by the observers' preconceived ideas.³ Nevertheless, it would be unjust to carp at the memoirs on mountain fever that were written by W. T. Ewing,⁴ by Roberts Bartholow,⁵ by John J. Milhau,⁶ by Charles Smart,¹⁴ and by Charles F. Kieffer,⁴⁰ as those observers deserve great credit for recording accurate and succinct descriptions of the disease as observed by the unaided eye.

What has been most remarkable is not the essential inadequacy of early descriptions of the mountain or non-exanthematic tick-fever, but the fact

that it has been necessary for the present writer to re-discover it, at least from the aspects of calling attention to its existence and of establishing it as a separate disease entity.^{47, 48}

The non-exanthematic tick-fever of the mountains has a characteristic clinical course, but a course that varies with its virulency to range from a mild, remittent-recurring type of fever to a severe typhoidal form. In the latter type the fever is so continued as to virtually obscure the remittent and recurrent characteristics. Some cases commence with marked remittency of the fever but pass into a continued fever, high or low, with more or less stuporousness and prostration. These two types, the recurrent and the continued (with more or less remissions) have been noted by most observers. They were treated as separate types by Kieffer,⁴⁰ and will provisionally receive like treatment by us, but with the qualifying remark that the continued form is very probably tularemia, but has not yet been proven to be so. These types are not absolutely fixed but are observed to somewhat intergrade with one another, which lends color to the belief that mountain fever may occasionally take a continued fever

*Received for publication, Aug 29, 1931

form In some localities the recurrent type of the fever is more characteristic than in other localities, thus in the Black Hills and in Wyoming the fever is predominantly recurrent whereas in Colorado and Utah it is more commonly observed to have one well marked major episode followed by one, or at the most two, very minor exacerbations A distinct tendency to a remittent and recurrent character can, however, be almost always made out even in the so-called continued type, and similarly in the Colorado-Utah type with one major episode, the recurrences are often so minor in character as to frequently attract no special attention

CLINICAL COURSE

With but very few exceptions, the *incubation period* is four days Longer incubation periods have been observed but seven days is the longest authentic instance Kieffer observed a case with an incubation period of three days

The *prodromes* consist of extreme weariness and faintness (languor), loss of appetite, muscular weakness, and an "empty or sinking feeling" in the epigastrium They merge with and continue throughout the onset, which usually occurs within two to eight hours after the first appearance of malaise

The *onset* is sudden with profound chilliness (but with no rigor) lasting from one to two hours and alternating with occasional flashes of heat The cold stage is suddenly succeeded by a rapid accession of fever, accompanied by excruciating pains in the back and loins, and to a somewhat less extent throughout the body, especially the posterior cervical region and the extremities, with occasional cramping

of the legs A diffuse dull headache, chiefly frontal, occurs commonly but is rarely severe, although occasionally intolerable The muscles become tense and the small muscles twitch, particularly the orbiculars and those of the face Nausea is usually noticed Vomiting is usually absent in adults but may occur in children, although not as commonly as in other fevers The face becomes flushed, the facies tense and troubled, the skin hot and dry, the tongue red and swollen ("strawberry tongue"), the conjunctivae very markedly congested, but lachrymation does not occur

The pulse, at first rapid (85 to 90), full and bounding, becomes, after a few hours, very rapid (120 to 130), thin and tense and continues so for twenty-four to forty-eight hours

The *fastigium* is characterized by a fever of 103.4° to 104.6° F, by the patient lying motionless, for fear of pain on motion, but with a clear though restless sensorium, sleep being impossible, or broken and troubled Breathing is shallow, a trifle quickened and sighing Meteorism does not occur

Constipation is the all but invariable rule throughout the course of the disease, the patient usually going four or five days without defecating Should evacuation take place spontaneously there is great tenesmus and pain in the anus, the feces being scybalus and covered with mucus, frequently blood tinged

The tongue, at first congested ("strawberry tongue"), becomes swollen, large and flabby, with a

very thick, moist bluish-white glaze of pasty (cheesy) consistency to the very tip, latterly cracking down the center. The tongue is tremulous when protruded.

Urination is impeded by muscular tenesmus, or almost entirely suppressed, or if any urine is passed it is scanty and highly colored, causing scalding when voided.

The liver and spleen, and all the muscles are tender to touch, the deep bone and joint and muscle pains continuing, but without redness or swelling of the joints.

Perspiration begins gradually and continues scanty for twenty-four to thirty-six hours, to end in a moderate (but seldom drenching) sweat coincident with the rapid lysis that ends the febrile period at the end of the second or early part of the third day. With defervescence, the congestion of the conjunctivae and face, the headache, and muscle aches, subside, the patient being left free from pain, but prostrated.

No erythema or other cutaneous manifestation develops at any time, but after the final defervescence a fine branny desquamation of the skin may occur.⁴ The latter is not common and seems due to medication with antimony or arsenic.

On the fourth day after the first accession of the fever, the patient feels very well, and desires to be up and about, but on the fifth to sixth day in a large proportion of the cases the fever, weariness, and muscle pains return, but with much less severity than at first, and last only from twelve to eighteen hours. After this recurrence subsides the

patient convalesces slowly, except that there may be one or two more recurrences of the fever to a slight degree.

On and after the fifth day the countenance assumes a dull despondent expression, the face a dirty yellowish hue, with a tinge of dark brown in the cheeks.

Usually the total duration of the disease is eight or nine days, although not uncommonly ten days. Very exceptionally it may be as much as fourteen to twenty-six days, especially so when of the continued fever type. Some slight cases run their course in five or six days, but some of the latter cases, if observed under the advantages of hospital care would be recognized as of the eight day duration.

Convalescence is characterized by marked anemia, by a persistence in the sensation of weariness throughout the whole body, and weakness and stiffness of the joints of the extremities. The carpo-metacarpal, metacarpal-phalangeal, and phalangeal joints are sometimes especially stiff and painful.¹⁴ Bartholow believed that "In many instances, the first evidence of commencing convalescence, was a violent pain in the soles of the feet, increased at night."¹⁵

VARIATIONS IN THE CLINICAL COURSE

The prodromes very exceptionally drag on for two or three days (in cases with a seven day incubation period), but more commonly than being prolonged they are less than three hours in duration, the disease striking suddenly. Very frequently slight muscle pains are noticed during the prodromal stage, but they do not become excruciating.

ating until the onset The onset is never free from pain, but in mild cases the muscle and bone pains develop gradually after the initial chilliness has passed off The initial epigastric distress is sometimes described as a hunger pain

The chilliness is sometimes so slight as to escape the observation of the patient Sometimes the initial chilliness is distinctly intermittent, alternating every fifteen minutes to one hour with like periods of sweating and a sense of heat, the intermissions occurring approximately hourly for the first twenty-four hours, or until the fastigium is well established

Nausea is very variable, in some outbreaks being a prominent symptom and occurring frequently before or with the onset of the chilly (initial) stage If it has not occurred during the invasion it is extremely unlikely to occur during the fastigium Vomiting occurs fairly frequently in children, but not as commonly as in other fevers In adults, vomiting almost never occurs, or at least not without great difficulty (about ten per cent of the cases) due apparently to a cardiospasm On the other hand, there are exceptional cases in adults in which vomiting occurs repeatedly with each onset of a febrile paroxysm

The headache is occasionally described by patients as being intolerable, and feeling very much as if the head were being mashed between rollers

The perspiration is occasionally established early and gives a cold clammy feel to the skin after the initial chilliness has existed for an hour or so Equally frequently the skin is hot and dry, and moist and cool by turns, alter-

nating at eight to twelve hour intervals The perspiration of the rapid lysis is always marked, and occasionally deserves the characterization of a drenching sweat, but usually it does not On the whole, very noticeable hyperidrosis is not a characteristic of mountain fever

A low, more frequently violent, delirium may occur during the fastigium, and recurrently at the height of each febrile paroxysm It is most likely to be observed in alcoholics, nephritics and others with an impaired metabolism

Occasionally, but very exceptionally, the bowels become spontaneously relaxed after the second or third day (once only as a rule) The stools, dark brown and watery and containing scybalous masses, are extremely offensive in odor Meteorism has been observed in exceptional instances

In mild cases the patients do not go to bed but drag around complaining of feeling "out of sorts", stupid and sleepy, with loss of appetite, constipation, and aches and pains in the bones and joints, or "neuralgias"

The fever typically lasts for forty-eight hours and recurs with less intensity after an intermission of forty-eight hours, the paroxysms of fever and intermissions being each of two days duration, but the fever becomes progressively less severe with each remission A general type of regularity can be made out, and some of the early epidemics described by army surgeons evidently ran with few exceptions to the regular type encountered during the epidemic described, but on the whole mountain fever is not as regularly remittent and recurrent as malaria is intermittent Irregularity of the

remittences and recurrences is common so that mountain fever is best described as a fever distinctly irregular but with marked tendencies to a regular type

The various observed febrile courses can be reduced to a graphical portrayal as follows

Numbers in parentheses represent days of fever, other numbers, days of intermission. Accents represent degree of intensity: two, severe; one, moderately severe; none, mild. Figures (2) (1) and (1) (1) mean that a nearly complete or very decided remittance occurs between the days indicated but lasts for only a relatively brief time

v=vomiting, d=delirium, =convalescence, x=one, two or three additional (usually mild to moderately severe* recurrences)

(2)" 2 (2)' 2 (1)	16 per cent
(2)" 2 (1) 3 (1)	5 per cent
(2)" 2 (2)' 2 (2) x	6 per cent
(2)' 2 (2)" 2 (2) x	3 per cent
(2)' 2 (2)" 2 (1)	5 per cent
(2)' 2 (2)" 2 (1) 1 (1)	3 per cent
(2)" 2 (1)'(1) 2 (1) 1 (1)	10 per cent
(2)" 2 (1)'(1)' 2 x	5 per cent
(1)"(1)' 2 (1)(1) 2 (1)	5 per cent
(1)"(1)" 2 (1)'(1) 2 (1)	5 per cent
(1)"(1)" 2 (1)'(1) 2 x	2 per cent
(3)" 2 (2)' 1 (1)	10 per cent
(2)"(1)' 2 (2) 1 (1)	6 per cent

*These percentages merely represent our impression as to the approximate frequency with which the different combinations of remittance and recurrence occur. It is not to be supposed that the above groups exhaust all combinations that may be encountered, but they well exemplify the "irregular regularity" of mountain fever.

The 'days' as given, particularly as referring to the days of intermission, are not to be understood to be exact periods of twenty-four hours. In fact there is not as exact a diurnal cycle seen in mountain fever as in the paludisms.

PHYSICAL FINDINGS

The marked conjunctival engorgement has already been noticed. Epistaxis may occur but is decidedly uncommon. The fauces are normal or slightly injected but never extremely hyperemic. There is no buccal endanthem. Cervical and other external adenopathy is not noticeable.

Chest findings are not a part of the disease but a secondary bronchitis sometimes follows the disease when inclemencies of the weather have been experienced during the pyrexial period.

Abdominal discomfort, always present to some extent, is vague, variable, and inconclusive. Rigidity and hyperesthesia, and pain on deep palpation, are to be discounted as the patient is hyperesthetic and tense over the whole body. The spleen becomes barely palpable early in the course of the disease but does not become more than slightly enlarged. The liver is always tender and sometimes a trifle enlarged. A distended bladder may be encountered.

DIAGNOSIS

Mountain fever is particularly devoid of characteristic (pathognomonic)

physical findings Not one of the physical findings may not be found in some other fever or even group of fevers The nearest approach to an exception is the tongue, which is fairly characteristic, and yet by no means pathognomonic Hence diagnosis must rest, in the present state of our knowledge, upon a consideration of the attending circumstances (locality, season, history of tick bite or of exposure), exclusion of other possibilities, and upon the appearance of the clinical phenomena as a whole, the latter being unique when considered with respect to their syndrome and evolution The differentiation from the two most clinically similar diseases, dengue fever and relapsing fever, will be discussed under the heading of nosography

Owing to the history of tick-bite, the disease that gives rise to the greatest practical difficulty is spotted fever of the Rocky Mountains Where mountain fever and spotted fever co-exist locally it is not to be supposed that mountain fever can always be distinguished from spotted fever during the first two days of its course After the second or third day, however, spotted fever should be excluded by a consideration of the following clinical differences

Spotted fever has a somewhat less stormy onset with a more protracted accession of fever, with a continued and prolonged (and usually ultimately higher) character, with only slight or moderate remissions Important, also, are the lesser intensity of spotted fever's muscle and bone pains, the stupor developing in spotted fever after the second or third day (even in mild cases, although not in the mildest, ambulatory, type) The lesser degree of nausea but the more marked cyanosis and hyperidrosis in spotted fever are

usually noticeable after about thirty-six to forty-two hours The puffy facies of spotted fever contrasts with the pinched facies of mountain fever The spotted fever case lies relaxed, "log-like", the mountain fever case is more tense, for fear of pain on movement In spotted fever insomnia is all but absolute, in mountain fever it is only relative, sleep occurring fitfully A dry cough, with or without a small amount of very tenacious mucus, occurs with the prodromal stage or onset of spotted fever but is not present at all, or only very late, in the course of mountain fever By the fifth or sixth day the spleen is larger in spotted fever than in mountain fever The tongue tends to remain more swollen and much less coated in spotted fever than in mountain fever, and frequently cannot be protruded in spotted fever Finally one of the most helpful and invariable differences is the absence of the characteristic lenticulo-macular (initially slightly raised) erythematocyanotic (frequently hemorrhagic) exanthem of spotted fever, which first appears on the ankles and wrists and extends upwards to cover the trunk but (usually) spares the face A perhaps inconstant difference, and yet one helpful at times, in the early course of the disease, is that the abdominal symptoms of spotted fever at onset suggest an acute cholecystitis (or hepatitis) whereas those of mountain fever suggest a cardiospasm with ulcer or gastric dilatation symptoms

As the continued form of mountain fever may be very difficult or impossible to distinguish from mild or aberrant types of typhoid fever and the paratyphoids, no attempt will be made to describe the (inconstant) clinical differences except to call attention to the semi-liquid stools, the occipital instead of frontal headache, the small, dry tongue, the ultimate bradycardia, the greater wasting of body tissues, the scaphoid abdomen, and the odor of body and breath encountered in the enteroides group It is of course understood that agglutination tests or

blood cultures may be necessary for definitive diagnosis for both the enteroid group and tularemia, which will also frequently have to be taken into consideration

Acute epidemic influenza has undoubtedly been mistaken for mountain fever, and accounts for some of the so-called mountain fever reported in the winter months¹⁰ The much greater irregularity of its remittances, the profuse lachrymation, rhinorrhea and sneezing, the acutely congested pharynx, with frequent secondary otitis and nasal sinusitis, the symptoms of bronchial involvement, the larger, more compressible pulse, the more superficial character of the muscle aches, with particular predilection for the intercostal and cervical groups, the (occasional) singultus, and the tendency to a critical or epicritical diarrhea, make up a clinical picture that ought not to be mistaken for mountain fever.

Regional septic processes, perinephric abscess for example, may cause a heavily coated tongue and an irregularly-regular type of remittent fever, but with them the generalized intolerable "break-bone" pains are absent, whereas a sharp, knifstab-like, or deep "hot iron," regional pain is present

PATHOLOGY

No necropsy material has been available

The *urine* shows nothing noteworthy During the prodromal stage the patient often passes much clear urine of low specific gravity The urine drawn during or after the fastigium is of high specific gravity, acid, and with excess of pigments and bladder epithelium, but is free of sugar, ace-

tone, bile and albumin unless some renal impairment has already been present Hyaline casts may be found

The *blood* shows a profound change, especially so considering the intensity and short duration of the fever The red cells become greatly reduced; in severe cases to 3,000,000 or even to 2,500,000, which is less than fifty per cent of the normal red count at high altitudes Hemoglobin diminishes in ratio with the red count, the color index remaining 1, although when regeneration commences the red cells increase at greater rate than the hemoglobin, the index falling below 1. The anemia is predominantly a toxic, aplastic, rather than a hemolytic anemia, although the muddy color of the face late in the disease suggests the occurrence of some hemolysis.

Neither a leucocytosis nor a leucopenia develops although the white count tends to range a trifle above normal The differential count shows a constant increase of the large mononuclears (150 to 165 per cent) with lymphocytes around ten per cent and eosinophiles under 1 per cent The large mononuclears are increased absolutely as well as relatively, a condition also noted in spotted fever

The absence of jaundice speaks for very little derangement of the liver or bile ducts

Numerous cases of mountain fever studied repeatedly in the laboratory at the Post Hospital of Fort D A Russell have shown conclusively that the serum of mountain fever does not contain the typhoid organism nor agglutinate the latter

So far, numerous efforts to establish the disease in guinea-pigs have failed

This is one of the best evidences that the virus is distinct from that of spotted fever

PROGNOSIS

In mild cases convalescence is more rapid than in dengue but in severe cases it may be prolonged for weeks. Organic complications or local sequelar infections do not develop, except very rarely the cutaneous pyodermata in those who are uncleanly and already debilitated, with chronic foci of staphylococcic or streptococcic infection.

Mortality is not indisputable, but is extremely rare at best. In the early literature several deaths attributed to the continued form of the disease were recorded but the true nature of these cases is uncertain, much of the severe, so-called mountain fever undoubtedly having been typhoid fever^{16, 17, 20, 26, 33} or tularemia. And yet there is no reason why a severe case of mountain fever should not carry off a debilitated individual or a patient embarrassed by cardiac insufficiency.

TREATMENT

The patient should be put to bed and made comfortable, blankets and hot water bottles, or tepid sponging, being used according to the stage of the disease. A large hot toddy or hot lemonade is grateful. Emetics were formerly much employed but are of doubtful value unless retching is continued and troublesome.

During the initial episode, and severe recurrences, morphine should be given hypodermatically in effective dosage every four hours, as it alone relieves the excruciating bone and muscle pains. For the milder recurrences, acetphenetidm or the less efficacious acetylsalicy-

lic acid will be satisfactory, acetanilid should be avoided. To quiet the sensorium a hypnotic such as barbital, fifteen or twenty grains, should be given and repeated as necessary, or a bromide in sixty grain doses is usually sufficient, chloral hydrate should be avoided. A collyrium of half saturated boric acid solution to which a fifth-part of epinephrin chloride solution (1-1000) has been added is grateful to the eyes. If photophobia is noticeable a dark cloth should be placed over the eyes unless the room can be completely darkened. An alkaline, antiseptic mouth wash should be prescribed for frequent use. An isotonic solution made of equal parts of salt and baking soda does equally as well. The bowels should be moved, preferably by enema in the early stage of the disease, but, as soon as the onset has passed off, by a saline cathartic or by a hydragogue cathartic pill, such as the calomel-rhubarb-colocynth pill, repeated daily for two or three days. The bladder should be watched, and if necessary to prevent distension, the urine should be drawn. Digitalis is rarely indicated, as in spotted fever, except in the continued fever type of the disease, when it is well to start it early.

Other than to place the patient on a sensible fever diet, with thought being given to the constipation, no special dietary restriction is necessary. During convalescence, the severe anemia should be combated by means of an iron, arsenic and copper hematinic, and cod liver oil according to indications. For ending the persistent joint aches, a short course of sodium or potassium iodide in large dosage, with or without

a little Fowler's solution, is distinctly valuable

There is no known specific for the disease. Quinine was formerly much employed, and much abused, but impartial observers as Milhau⁶ and Kieffer,⁴⁰ early discovered that it not only had no effect on the fever but in large doses did harm by increasing the subjective symptoms.

Kieffer attached considerable value to subcutaneous injections twice daily of one or two cubic centimeters of a one per cent solution of sodium arsenite to which four per cent cocaine hydrochloride was added to control the pain. We feel that neither the sodium arsenite nor sodium cacodylate injections are necessary, but that Fowler's solution by mouth in appropriate but fair-sized dosage will do as much good. It should not constitute routine treatment but should be reserved for cases that continue to run a fever after the seventh day, or have protracted muscle aches and joint pains.

NOSOLOGY

The non-exanthematic tick-fever of the mountainous West evinces a syndrome not unlike, in some respects, the clinical course of two diseases, each of which is the type of a different disease category, namely dengue fever and relapsing fever. As to which category it is more nearly correct to assign the American mountain fever can be determined for clinical purposes, but for a final assignment on the basis of bacteriological and pathological evidence it will be necessary to await the study of the virus of mountain fever. Other fevers have a recurrent clinical course, such as undulant fever (brucel-

lasis, melitococcemia) but it would for the present seem to labor a point to go beyond a consideration of mountain fever's two most presumable cognate affinities.

Compared with the relapsing fever group we find that mountain fever and the relapsing fevers are arthropod-borne diseases, that neither are invariably exanthematous; that both are characterized by a marked secondary anemia, and that both have well marked recurring or relapsing characteristics. There are these differences however: the relapsing fevers are caused by *Spirochaeta* that are not difficult to recover from the blood at some time during the clinical course; they are notable for being truly relapsing virtually to their final episode, which is seldom the second or third relapse. They prostrate, but do not cause the profound bone, joint and muscle pains that are practically a fixed character of mountain fever. The relapsing fevers have a comparatively insidious onset and a much greater interval between relapses than does mountain fever. They frequently cause a bronchitis and a disorder of the cornea not observed in mountain fever. Finally they are of the bilious type with icterus occurring in one-fourth to one-half of the cases, according to the severity of the epidemic.

Compared with dengue fever we find that mountain fever is of like short duration, that it is, like dengue, more properly called recurrent than relapsing, and that the disease is of equally, or nearly equally, abrupt onset. It has in common the "break bone" symptoms, the congestion of the conjunctivae, and the absence, or virtual ab-

sence, of bronchial involvement Mountain fever differs from dengue fever in lack of a palmar and plantar erythema and a generalized erythematous or polymorphous eruption. Also there is not the cervical adenopathy that one finds in thirty per cent to seventy per cent of the cases of dengue. Lachrymation occurs in dengue but not in mountain fever. The tongue is not greatly different in the two diseases although more heavily coated in mountain fever. Constipation is not so absolute in dengue, purging being observed in about one-third of the cases. Mountain fever differs in producing a far greater anemia and in not being accompanied by the characteristic and well marked leucopenia of dengue. In both fevers there is an increase of the large mononuclears, but the eosinophiles are increased only in dengue.

From the above comparisons it will be observed that mountain fever has an intermediate position between the short fevers of the dengue type and the protracted fevers of the relapsing fever group. Similar in some reactions to the one and yet in other reactions more closely resembling the other, it serves almost as a 'connecting link', were one to take cognizance of the theory that dengue is a spirochetal disease. We do not wish it understood that we are asserting a theory of mountain fever's spirochetal nature, but when one considers the comparative difficulty with which the *Leptospira icterohemorrhagica* is recovered from the blood in the spirochetal type of infectious jaundice, a protozoan of some such character may occur in the blood of mountain fever, and yet have escaped detection. In this connection it should not be for-

gotten, however, that Noguchi recovered from the mountain fever tick, *Dermacentor andersoni*, a filterable virus that was demonstrated not to be the virus of spotted fever⁴⁴. Whether the filterable virus recovered by Noguchi is that of mountain fever remains to be ascertained.

Apparently mountain fever has closer affinities to dengue fever than to relapsing fever but whether the resemblance is sufficient to warrant grouping it provisionally with dengue fever may well be a matter of opinion, but, keeping in mind that it is but tentative, it would seem permissible clinically to group mountain fever with dengue fever.

THE CONTINUED FORM OF MOUNTAIN FEVER—POSSIBLY TULAREMIA

Appearing from the outstart as a continued fever, or more commonly becoming a low continued fever after an initial phase with remittences, this type of mountain fever tends to a longer course than the remittent type. Two weeks to twenty-six days is the usual duration, but in Colorado and Utah, and occasionally in Wyoming, a shorter fever of nine or ten days may be predominantly of the continued type, although some minor degree of remittance can usually be made out.

The continued form is somewhat typhoidal as far as the fever and the nervous system are concerned, but with those exceptions there is not a close resemblance to typhoid fever. The continued form seems to be a lower grade of infection limited largely to the blood stream. In it the muscle-bone-joint pains and other localizing phenomena are not nearly so severe. Towards the

end of the disease the patient is weaker and more emaciated than after the short recurrent type, but convalescence is not thereby prolonged, it being by no means unusual for these cases to convalesce somewhat more rapidly than those who had a typical recurrent type of American mountain tick-fever but continued to have persistent bone and joint pains during convalescence

There is very considerable reason to suspect that the so-called continued type may not be due to the virus of American mountain tick-fever but to a *Bacterium tularensense* infection. The local lesions, acute but indolent skin ulcers at site of tick bites, typical of tularemia, occur following tick-bite in some of these cases, but they certainly have not been observed in all

Bilateral Double Kidney With Duplication of Ureters*

BY ROBERT M. LINTZ, M.D., Brooklyn, N. Y.

ANOMALIES of the various parts of the body are not infrequent, but with the exception of those of the spine those occurring in the genito-urinary tract are most often noted¹. One of the rather frequent anomalies of the genito-urinary tract is that of double kidney with duplication of renal pelves and of the ureters. Young and Davis² state that the *condition* of double kidney and ureter is not so rare, but that the *recognition* of the condition is extremely rare. They believe that anomalies of the kidney and ureter are much more frequent than is generally appreciated and that among such kidneys a relatively large number show pathological changes, malformation predisposing to disease.

Various types of duplication of the ureter with the accompanying double kidney have been reported from time to time. It is possible to have unilateral involvement with the other side normal or both sides may be changed from the normal. In the condition known as complete duplication of the ureters there are separate bladder orifices for each ureter with the ureters running from the pelves to the bladder. This means that where there is

complete bilateral duplication there are four ureteral orifices present in the bladder. In the incomplete form of duplication there is union of the duplicated ureters somewhere between the emergence from the pelves and the entrance into the bladder. In these cases the bladder may present the usual appearance as far as the ureteral orifices are concerned. Where there is complete duplication of one side and either a normal opposite side or incomplete duplication of the opposite side three ureteral openings into the bladder will be present.

Thompson³ reported fifteen cases of duplication of renal pelves and ureters in 1735 consecutive autopsies at London Hospital and three cases in 11,133 consecutive autopsies performed at Guy's Hospital and at Victoria. It is interesting to note that of the eighteen cases of duplication sixteen were females. Mauclair and Sejourne⁴ found the ratio of occurrence in females to males to be 7 to 3. Thompson's observation is at considerable variance from those of some of the earlier investigators. Wagner,⁵ Poirier,⁶ and Bostroem⁷ in large autopsy series found the frequency of complete and incomplete duplication of the ureters to be from three to four per cent. Braasch and Scholl⁸ cited 144 cases of

* Received for publication, May 8, 1931.

duplication of renal pelves and ureters of which thirty per cent were complete and seventy per cent incomplete. Of these 144 cases there were only eight (5.5 per cent) in which bilateral duplication of pelves and ureters was present and all of these eight did not have four bladder orifices for the ureters. These authors also noted that 37.5 per cent of the cases presented some pathology of the urinary tract. Harpster, Brown and Delcher⁹ in a review of the cases of duplication of the ureter in the literature up to 1922 found complete duplication in 58.1 per cent of the 382 cases reported up to that time. They recorded 181 instances of complete unilateral duplication, 40 of complete bilateral duplication, 133 of incomplete unilateral duplication, and 28 of incomplete bilateral duplication. They believe that only a very few cases of this condition are diagnosed pre-operatively, the difficulty being increased when the cystoscopic examination shows but two apparently normal ureteral openings in their usual positions.

From the number of cases of this form of anomaly of the urinary tract that are cited one might conclude that this condition should be encountered

infrequently in practice. That the diagnosis is seldom made is well known. The figures that have been quoted are derived from autopsy records or from observations made on a large series of operative cases. Mertz,¹⁰ in 1920, compiled a list of the cases of duplicated ureters recorded to date. He came to the conclusion that many cases are discovered only post mortem and that of those diagnosed during life and before operation the diagnosis

was possible only after repeated urological and x-ray examinations.

My purpose in here citing another case of bilateral double kidney and ureters is twofold: first, to point out that with the aid of newer laboratory methods this condition should be diagnosed more frequently; second, to show that the responsibility for this diagnosis need be borne no longer solely by the urologist but that the responsibility rests upon internist and the general practitioner as well, with the aid of the roentgenologist.

REPORT OF CASE

Case. A single woman, a school teacher, age 52, came October 18, 1930, complaining of pain and discomfort in the left lower quadrant of the abdomen and in the left lumbar region, the latter radiating at times down the left thigh. The pain had been present for as long as the patient could remember but had recently become more annoying. Lately there had been frequency of urination; she noted that on urination there was accentuation of the pain of the left side of the abdomen and of the left thigh. For the last four years there had been epigastric distress after eating, during this interval the patient was frequently awakened from her sleep by migrainous headaches. There was nothing of significance in the previous history. The family history was interesting in that her mother died at the age of 45 years with carcinoma of the bladder and one sister has been told that she has calculi of the urinary bladder.

The patient was well developed and very well nourished. Her height was 5 feet 1½ inches and her weight was 161 pounds. There was a systolic murmur over the apex of the heart which was considered as functional in nature. There was marked tenderness to palpation below the right costal border over the area of the gall bladder. No lumbar tenderness was noted. Other features of the physical examination were essentially normal. The blood pressure was 122/90. A tentative diagnosis of gall bladder disease and nephrolithiasis was made.

The patient had 4,220,000 erythrocytes and 6,700 leukocytes. The differential count showed 60 per cent polymorphonuclears, 2 per cent eosinophiles, 2 per cent large lymphocytes, and 36 per cent small lymphocytes. The hemoglobin was 90 per cent (Sahli). Repeated examinations of catheterized urine showed a few white blood cells and numerous red blood cells.

Cholecystography (after the oral administration of tetra-iodo-phenolphthalein-sodium) showed a gall bladder that filled satisfactorily and was reported as normal in size and shape and regular in contour. In the fundus of the gall bladder there was a small circular filling defect about the periphery of which there was a thin dense shadow. This concentric rim was visible two hours after the gall bladder had been emptied of the dye by the ingestion of a fat-full, mixed meal. A report of cholelithiasis was made.

It was considered unlikely that the biliary calculus was accountable for the left sided pain. Due to the persistent presence of blood cells in the urine the diagnosis of renal calculus was further advanced. The kidneys were x-rayed and there was no evidence of calculi. Both kidneys were reported as being considerably larger than usual. The patient was then given 40 grams of Uroselectan (sodium salt of 2-oxo-5-iodopyridine-N-acetic acid) intravenously. Twenty minutes after the intravenous injection of the dye there was a very clear visualization of two renal pelves on each side from each of which a ureter came off (figure 1). On both sides the more superior pelvis consisted of but a single calyx while the inferior and larger pelvis had two major calyces. A moderate degree of hydronephrosis of the two lower pelves was reported more pronounced on the left side. On each side the ureter from the superior pelvis was situated medial to the one from the inferior pelvis. A picture made forty-five minutes after the dye had been injected gave no additional information. In the picture made sixty minutes after the dye had been given (figure 2) the ureters in their lower course are well seen. On the left side two distinct shadows placed very close together are noted down to the level of the symphysis pubis. Below this a single wider shadow is noted

entering the bladder. It could not be ascertained definitely from the picture whether this represented a union of the duplicated ureters or whether it was due to overshadowing of the separate ureters. Although the right side did not show this condition so clearly, a similar arrangement could be made out on very close inspection of the films. The patient was referred for cystoscopic examination, but inasmuch as she refused this examination it could not be definitely made out whether two, three, or four bladder orifices were present.

Papin and Eisendrath¹¹ pointed out that the ureter belonging to the upper pelvis always ends lower and more medially. In addition, they state that when there are two ureters from one kidney there are always two pelves on that side—no case has ever been shown to be otherwise. Bugbee and Losee¹² held that the presence of a double ureter means the existence not only of two pelves but also of two physiologically separate kidneys on the side involved, although these may be fused anatomically to represent a single organ. Braasch and Scholl⁸ were of the opinion that hydronephrosis is the most common pathological complication of duplication of the ureters. They believed that this is most probably due to the fact that there is ureteral obstruction in the region of the junction of the two ureters in incomplete duplication. Harris¹³ was of the same opinion and added that there is usually nothing in the history or physical examination to lead one to suspect anomalies. Thompson found that the combined capacity of the pelves in double kidney may be less than that of a single normal pelvis. In such cases the gradual constriction of the normal pelvis may be replaced by a very sharp one, making the discharge of urine

FIG 1 Twenty minutes after the intravenous injection of the dye. The arrow indicates the biliary calculus, this might easily be mistaken for a renal calculus if cholecystography had not been successful

FIG 2 Sixty minutes after injection of the dye On the left side the course of the lower part of the ureters is clearly seen

more difficult. He believes that at times pain and slight pyuria can be explained only on the basis of double small pelvises with reduplication of ureters.

EMBRYOLOGY

The following brief summary of the embryological development of the urinary tract is taken mainly from the article of Young and Davis.² During the embryological development of the higher vertebrates there are three successive types of excretory organs. These are the pronephros, the mesonephros, and the metanephros—the latter becoming the permanent kidney. All three types come from the mesodermal blocks known as the nephrotomes. The nephrotomes consist of a series of blocks of mesodermal cells situated longitudinally along both sides of the neural canal and are between the primitive segments and the lateral mesodermal plates.

The Wolffian duct—the excretory duct of the mesonephros—is formed from the pronephros. The mesonephros arises from the nephrotomes that extend from the fifth cervical to the third lumbar segments and consists of a series of glomeruli and tubules opening into the common duct. In man this structure atrophies. According to Kelly and Burnam¹⁴ the mesonephros is at the height of its development during the fourth and fifth weeks of embryonic life. The mesonephros atrophies during the eighth to sixteenth embryonic weeks, the Wolffian duct persisting as the vas deferens in the male and as the rudimentary Gartner's duct in the female.

The Wolffian duct opens into the cloaca and it is near this juncture that

a budding occurs which is the anlage of the permanent kidney. From this bud is formed the ureter, pelvis, calyces, and collecting tubules while the secreting portion of the kidney is formed from a collection of mesodermal cells known as the metanephrogenic tissue. This latter mass of tissue surrounds the tip of the ureter bud soon after its formation.

The ureteral bud, capped with metanephrogenic tissue, first grows dorsally toward the spine and then turns cranialward. The tip of the bud at the 6 mm embryo stage has become bulbous and as early as 8 mm a bifurcation of the primitive pelvis occurs, the first evidence of the calyces. During the ascent of the kidney the uro-rectal septum appears, dividing the cloaca into what is to be rectum and bladder. Young and Davis believe that in double ureter the cause may be ascribed to premature or exaggerated bifurcation of the ureteral bud, the split extending varying distances down the ureteral stalk instead of being confined to the primitive pelvis.

COMMENT

The frequency of the occurrence of double kidney with duplication of the ureter and the very infrequent diagnosis made of this condition suggests that there is generally a nearly complete absence of symptoms that might be termed characteristic. When a patient does give a story that might be referable to the urinary tract, such an anomaly is rarely considered. With the aid of cystoscopic examination the frequency of diagnosis of double ureter is somewhat increased, but still the possibility of missed diagnosis is too great.

Assuming that retrograde pyelography is employed it is usual to visualize but one ureter where there is incomplete duplication. A reflux of the contrast medium into the lower portion of the accompanying ureter is usually the first hint of duplication of the ureter.

Where a history and physical examination are suggestive of an indefinite disturbance of the urinary tract the physician should consider the possibility of double ureter. With the introduction of intravenous pyelography the diagnosis becomes quite easy and very certain. This method, as is well known, is easy of application. The certainty with which the diagnosis is made or ruled out in kidneys of good function is apparent. Employment of this method makes for a more comfortable and satisfied patient. Where intravenous pyelography is used it may make cystoscopic examination unnecessary—a procedure to which many patients object both before and after its accomplishment.

It is to be expected that the pre-operative diagnosis of double kidney and double ureter will be more frequent. The presence of this condi-

tion can usually be determined very satisfactorily by the internist or the general practitioner with the aid of an x-ray study.

CONCLUSIONS

1. The occurrence of double kidney with duplication of ureters and kidney pelves is not rare, but the diagnosis is seldom made.

2. Pain in the lower quadrant of the abdomen and in the lumbar region of the same side radiating down the thigh, frequency of urination, red blood cells and white blood cells in the urine, should lead one to consider the possibility of this anomaly after renal calculi have been ruled out.

3. Duplication of ureters and pelves is due to an abnormal exaggeration of the usual embryonal development.

4. Intravenous pyelography enables easier and more certain diagnosis of double ureters and pelves than does cystoscopy.

5. With proper x-ray studies the internist and the general practitioner should make the diagnosis of this condition.

On the Treatment of Angina Pectoris

“THE spiritual side of the case must not be neglected in this disease in which the emotions play so important a rôle. The development of a philosophy of life, of the power of adaptation of desire to possibilities, the cultivation of hobbies of a restful character, such as suitable reading, music and such pacific occupations as painting, etching, carving and similar pursuits, are of real medical benefit. Habits of restfulness and relaxation are to be cultivated. Climate is often very important, and those who live in the temperate zones may well spend their winters in the South or perhaps go to live permanently in some mild, temperate and congenial climate. Few patients do well in the cold places or at high altitudes.”—(HARLOW BROOKS, M D, F A C P, *Am Jr Med Sci*, 1931, CLXXXII, 784-800)

Editorial

INTERNAL RADIATION IN THE CAUSATION OF MALIGNANCY

A few months ago reference was made editorially in the *ANNALS* to the known extrinsic factors having a carcinogenic or sarcogenic action. X-ray and other solar irradiation have both been recognized for many years as belonging in this group. That the radio-active source may be within the body of the victim, inseparable from him, diminishing in amount and activity only by its natural and unalterable decay, and at the same time be capable of inducing neoplastic proliferation in a startling conception. Martland¹ has demonstrated that this is exactly the situation which obtains with certain of the radium dial painters. Knowledge of this fact has a significance much wider than its application to this extraordinary occupational disease. It may explain the extrinsic factor in certain other forms of occupational malignancy and sounds a warning in connection with the indiscriminate internal use of sources of radio-activity.

The circumstances under which radium poisoning was recognized as an occupational disease are now well known. In a New Jersey factory there were employed for varying periods of time during the years 1917

to 1924, about 800 girls whose work was painting the luminous dials of watches and clocks. The paint consisted of phosphorescent zinc sulphide combined with small amounts of radium, mesothorium and radiothorium in the form of insoluble sulphates. Due to the habit of pointing the brushes used between the lips, small amounts of radio-active paint were ingested over extended periods. The possibility of absorption through the skin and by inhalation also existed. Subsequent investigations have shown that, while most of the paint ingested passed rapidly through the alimentary tract and was eliminated, a certain portion was stored in the body and particularly in the bones. After final deposition in the bones these radio-active substances emit their characteristic radiations continuously, diminishing only with the exhaustion of the deposit by the natural process of physical-chemical decay, a process so slow in the case of radium that a life-time makes no significant change. It has been found from material obtained at autopsy that the lethal amount of radio-active substances distributed in the entire skeleton may range from 10 to 180 micrograms, estimated as radium element. As Martland vividly states it, it is necessary to have only 10 micrograms (one one-hundred-thousandth gram) of radium bromide, distributed over the entire skeleton, to

¹MARTLAND, HARRISON S. The occurrence of malignancy in radio-active persons, *Am J of Cancer*, 1931, xv, 2435-2516

produce a horrible death years after it has been ingested. The damage in the radium dial painters is due to the internal bombardment with alpha particles, a type of radiation never before known to have occurred in human beings.

Martland has knowledge of 18 deaths, among the former employees of this factory, which can be strongly suspected of being due to so-called radium poisoning. Eight were proved to be such by autopsy. In addition, there are about 30 persons alive who are suffering from typical symptoms of radium poisoning or who, by virtue of their internal radio-activity, are liable to develop crippling lesions at any time. During the first six years after the development of this industry the ill-effects and resulting fatalities fell into two chief groups. One of these was characterized by a radiation osteitis, with a superadded bacterial infection in the case of the mandible and maxilla, so that extensive necrosis of the jaw preceded the fatal outcome. In the other group the continuous bombardment of the bone marrow resulted in a regenerative type of leukopenic anemia which resisted all efforts at treatment. During the years of this earlier period, that is, from 1922 to 1928, two dial painters died from osteogenic sarcomas. These were reported in 1929 by Martland and Humphries² who recognized that the incidence of two cases of sarcoma among fifteen examples of radium-mesothorium poisoning was too large

to be passed over as due to coincidence. This belief has now been fully justified for Martland's more recent report records the results of autopsy studies upon three more fatal cases of anaplastic osteogenic sarcoma, all of the victims coming from the group who worked in the New Jersey factory. In addition, he lists three additional living cases of probable osteogenic sarcoma from the New Jersey group and another fatal case in a girl who had worked as a dial painter in factories in other states.

In view of the known incidence of primary bone sarcoma in the general population, the occurrence of so many examples in the limited group exposed to this occupational hazard can have but one explanation—internal radiation has operated as a causal factor. Actual malignancy has been preceded by radiation osteitis, associated at first with a hyperplastic, irritative, compensatory bone marrow which is succeeded by a replacement fibrosis. The aplastic marrow of external irradiation is not found.

Knowledge of an occupational hazard should lead to its mitigation and eventual elimination. The demonstration of this sarcogenic agent has a wider significance, however, than its importance in the dial-painting industry. It affords a basis for a high degree of certainty that the occupational primary carcinoma of the lungs, which has been the most common cause of death among the cobalt miners of the Schneeberg district in Saxony for five hundred years, is best explained by the radio-activity of the ore. The air of these mines has a radio-active ema-

²MARTLAND, HARRISON S., and HUMPHRIES, ROBERT E. Osteogenic sarcoma in dial painters using luminous paint, *Arch Path.*, 1929, vii, 406-417.

nation content of from a few to 50 Maché units. A high incidence of primary carcinoma of the lung is said to have appeared among the workers in the pitchblende mines of Joachimsthal. It must be accepted that the deposit of radio-active substances in the body, particularly those producing alpha rays, may give rise to malignancy many years afterwards. From

this, it follows that the indiscriminate lay and quack use of radio-active waters, emanators, activators, etc., should be stopped. They are without therapeutic value aside from their psychic effect and may be doing an, as yet, unrecognized harm. It may be learned that even slight increase in the normal radio-activity of the human body is not without danger.

San Francisco—The City by the Golden Gate

SINCE the American College of Physicians will hold its Sixteenth Annual Clinical Session in San Francisco, April 4 to 8, 1932, it is appropriate to call attention at this time to certain facts of general and historical interest about the city in which we are to gather

San Francisco is not only one of the world's most beautiful and fascinating cities, it is also the center from which nine-tenths of California's scenic wonders can be most easily reached. Within a few hours' easy journey by train, stage or car are most of the places which tourists come thousands of miles to see. Yosemite lies due east, and can be easily reached in seven hours by automobile or train. Monterey Peninsula—one of the finest strips of sea coast in the world—is three and one-half hours by train to the south. The giant redwoods begin right in San Francisco's suburbs, at Muir Woods,

and can be visited in half a day's excursion.

Lake Tahoe, at the summit of the Sierra, is an easy night's or day's run by train or a short detour *en route* or returning. Shasta, Lassen, Sequoia National Parks, the Redwood Empire, the wine-grape valleys, Stanford and California Universities, Luther Burbank's gardens, Jack London's Valley of the Moon—all are within the circle of San Francisco excursions, requiring from a few hours to a day or two.

ONE OF THE WORLD'S TRULY COSMOPOLITAN CITIES

San Francisco is famous for its gay spirit, its Chinatown, its beaches, its picturesque waterfront, its flavor of Asia and the sea, its French and Italian restaurants, its Parisian touch. Not so many realize that it is also the business capital of the West and a seaport.

San Francisco's skyline from the Bay

Cosmopolitan scene

insurance, commercial and industrial enterprises that function from Chile to Alaska and from Salt Lake City to Shanghai and Singapore

A TOWN TO PLAY IN

From the days of the Gold Rush, San Francisco has believed in laughter and good living. People on the streets are happy and cordial. They smile easily. Good feeling and high spirits are in the air. You can't feel downhearted when you breathe the city's bracing sea-tang and see its hill rising in the sparkling sun above the blue Bay.

For scenic beauty, few places in the world can excel San Francisco itself.

Fisherman's Wharf

A tour of the city can be made as exciting and as filled with surprises as a first visit to some picturesque foreign town. The Presidio military reservation, founded by the Spanish in 1776, is one of the largest and most beautiful army posts in the country. Golden Gate Park is known around the world. The Ocean Beach and the Cliff House with its seal rocks, the public golf courses of Lincoln Park overlooking the Golden Gate, the eminences of Russian and Telegraph Hills, the quaint cable cars on the steeper streets, the picturesque foreign quarters, the glowing flower stands lining the curbs in the shopping district—all of these provide endless entertainment and diversion.

LURE OF THE SHIPS

Business and cultural metropolis of the Pacific Coast, San Francisco is first of all a great sea-port. In scenic grandeur, its great land-locked harbor ranks with Rio, Naples, and Constanti-

Montgomery Street, San Francisco

nople. To visit the waterfront, only a few minutes from the hotel and business section, is to feel one's self in touch with many strange far-off lands. You will see ships arrive and depart from Asia and the South Seas, for Latin America and Europe. You will hear strange tongues, see strange faces, smell the spice and fruits of the trop-

Market Street, San Francisco

Giant Redwoods in Muir Woods

ics, watch endless bales of raw silk swung from the hold of a great trans-Pacific liner. San Francisco is the gateway to the Hawaiian Islands, with frequent sailings via famous *de luxe* liners. San Francisco is the center from which American travelers, American ideas, and American goods are

carried to the hundreds of millions of awakening peoples inhabiting the great Pacific basin. Here the Orient and South Seas discharge their treasures. On these docks spill copra from the South Sea and Philippines, silks and teas from Japan and China, coffee and bananas from Central America, peasant ware from Spain and Italy.

PACIFIC ALLEY'S TREASURE-HOUSE OF ART

For eighty years the people of the Western Slope and of the Pacific Islands have looked to San Francisco for entertainment and instruction. To-day traveling Europeans are amazed by the treasures of its galleries, the excellence of its great orchestra, the vitality and stir of its cultural life. The Palace of the Legion of Honor, a

Mission Dolores, founded 1776

beautiful white marble replica of the famous Paris original, occupying a magnificent site commanding the Golden Gate and the open Pacific, holds priceless collections. So does the M. H. deYoung Memorial Museum in Golden Gate Park, and the beautiful California School of Fine Arts on Russian Hill. San Francisco has always been beloved by the stage, and its many theatres offer a variety of fare throughout the year.

Memorial Chapel at Stanford University

YOU CAN GOLF, FISH OR SWIM

Within twenty minutes of your hotel are golf courses where Bobby Jones could drive a ball from a putting-green high on the cliff right into the Pacific Ocean. Not even old Edinburgh has such a setting for its national game. You will be welcomed to the city's finest courses. Perhaps you would rather board a sturdy launch and fish for sea-bass or salmon in the Bay, or outside

the Heads in the open Pacific. It is easily arranged. So is trout-fishing in the Sierra or Coast-Range streams. For swimmers, there are the ocean beach, the famous in-door Sutro baths, and the Fleishhacker municipal open-air pool, the largest in the world.

YOU'LL FEEL AT HOME

The City is a paradise for those who enjoy good food. There are lit-

Memorial Stadium at University of California, Berkeley

Lincoln Park Municipal Golf Course overlooking the Golden Gate

DeYoung Memorial Museum, Golden Gate Park

erally thousands of restaurants and their rates are surprisingly low Food is important in San Francisco Restaurateurs are artists as well as business men Many are well-loved town characters You feel the difference And you like the friendliness It's a happy town Around the corner from the big hotels are Italian and French restaurants famous for a soup, a salad, a specially-prepared sea-food served with care and pride at low prices You can dine in China, Russia, Japan, Sweden, France, Spain, Italy or Germany by merely calling a taxi or walking a few blocks through streets rich in reminders that this is a great cosmopolitan sea-port For five cents you ride to the Beach, and lunch or dine with surf pounding outside and nothing

between you and Asia except the Pacific and a few islands Or you can mount Telegraph Hill, rising steep between the docks and the Latin Quarter, and sit at tables commanding a superb expanse of blue salt water and encircling mountains San Franciscans themselves like to go to Fisherman's Wharf, where the Madonna-blue boats bob with the tide, and dine in Italy on fresh-caught sea-food The Bay, the Golden Gate, and Mt Tamalpais look on you there

CHINATOWN

San Francisco's Chinatown is world famous Here are more dazzling displays of objects of art, silks, china and curious knick-knacks than are to be found in cities of China itself Here

San Francisco's world famed Chinatown

also are the two largest Chinese theaters outside of China, playing the weird dramas of Cathay with Chinese orchestras and every touch complete

SAN FRANCISCO'S DISTINCTIVE CLIMATE

In the summer it is America's coolest city—the warm California sun tempered by sea breezes and an opalescent reminder of sea mist which often takes the form, toward evening, of billowing white fog bringing the breath of the sea. Yet no circumstantial description of San Francisco can account for its peculiar appeal to the

visitor without taking into account a certain atmosphere of romance and charm that is instantly felt and that proves invariably winning to the stranger. It is compounded of the unusual physical setting and climate, of the happy, healthy people, of the high hills and stunning vistas, of the foreign settlements and the oriental flavor, and also of a long tradition of stirring and romantic days, from the Spanish down through the Forty-niners to the bonanza kings of the Comstock Lode, the builders of our first transcontinental railroad, and the more recent generation that built a great modern city on the ruins of the old.

Abstracts

A Study of 503 Cases of Pulmonary Tuberculosis with Indefinite or No Usual Abnormal Physical Signs By LAWRASON BROWN (Am Jr Med Sci, 1931, cixvii, 700-707)

"As far back as the beginning of the century, Osler, among others, recognized that extensive disease of the lungs could exist with few or no abnormal physical signs

I wish to present to you some conclusions I have arrived at from a study of some 503 such cases selected from 1900 consecutive cases at the Trudeau Sanatorium

The method by which a diagnosis of chronic pulmonary tuberculosis was established in these cases is that used for some years at the Trudeau Sanatorium The occurrence alone of either hemoptysis of a drachm or more, or of pleurisy with effusion, explainable on no other grounds, is considered to justify a diagnosis of suspected pulmonary tuberculosis in the absence of all other symptoms

The occurrence of moderately coarse râles or of a parenchymatous roentgen ray lesion (mottling, irregularly distributed) above the third rib and third vertebral spine was considered sufficient evidence for a positive diagnosis of pulmonary tuberculosis until disproved Tubercle bacilli in the sputum in the absence of lesions above the trachea must be considered as absolute proof of pulmonary tuberculosis The incidence of these five cardinal diagnostic data in 1367 cases diagnosed pulmonary tuberculosis from 1478 consecutive cases admitted to the Trudeau Sanatorium is as follows

	Per cent
Tubercle bacilli	61 5
Râles	68 5
Roentgen ray	99 0
Hemoptysis	33 5
Pleurisy	12 0

From the data here presented I am inclined to attribute considerable importance

in the diagnosis of pulmonary tuberculosis to the roentgen ray examination I am convinced it will reveal the lesions of the disease long before it is manifested in any other way "

Vioosterol Treatment in Experimental Hyperparathyroidism By HENRY L JAFFE AARON BODANSKY and JOHN E BLAIR (Proc Soc for Exp Biol and Med, 1931 xlix, 207-208)

Three groups of experimental animals (guinea pigs) were established To those in the first group viosterol was given daily for 7 to 10 days After this preliminary treatment, the animals were injected daily with parathormone in increasing amounts, and the viosterol was also continued This combined medication extended over a period of 23 days In a second group viosterol and parathormone were started simultaneously and administration extended over a period of 29 days The third group contained 6 controls which were injected with parathormone as in the second group, but these animals did not receive viosterol The animals in all three groups were killed to terminate the experiment and their bones were taken for histological examination They all showed decalcification and secondary fibrous invasion of the bones There was no consistent difference in the nature or severity of the lesions between the guinea pigs receiving viosterol and parathormone (groups 1 and 2) and those receiving only parathormone Under the conditions of this experiment irradiated ergosterol did not protect from the demineralizing effects of experimental hyperparathyroidism It is possible, however that the healing of bone lesions in experimental or clinical hyperparathyroidism might be promoted by viosterol after the state of hyperparathyroidism had been terminated by discontinuance of parathormone administration, or by the removal of a parathyroid adenoma

Nonsyphilitic Aortic Valve Deformity By B J CLAWSON (Arch Path, 1931, xii, 889-899)

Nonsyphilitic aortic valve disease is of two kinds active vegetative endocarditis, and deformity due to thickening and roughening with scar tissue and often with calcium deposits. The frequency, and particularly the etiology, of the latter type have been subjects of much discussion in the last few years. The author's series contains 93 cases of aortic valve deformity of the calcified nodular type. In 91 per cent of 68 cases in which this point was investigated, some degree of stenosis was present. It is evident that aortic stenosis of a grade recognizable clinically, and due to this type of valvular deformity, is far more rare. Both gross and microscopical findings in these valves tend to support the view that the etiological factor is an inflammatory rather than a metabolic (atherosclerotic) condition. The frequency of rheumatism in these cases, as indicated by a previous positive history, by the presence of an adherent pericardium or by an association of deformities in other valves, strongly supports the view of an infectious basis. It is doubtful whether a valve deformity severe enough to cause cardiac insufficiency is ever due to a metabolic disturbance such as arteriosclerosis. Accordingly the term 'arteriosclerosis valve deformity' should not be used in describing valvular insufficiency or stenosis.

Effect of Giving Digitalis on the Volume Output of the Heart and its Size in Heart Failure By HAROLD J STEWART (Proc Soc for Exp Biol and Med, 1931, xxi, 207-208)

The method of Grollmann for measuring the cardiac output was utilized in studying the effect of digitalis on the heart of normal individuals. Digitan (Merck) was given in a single dose of 0.8 gm to 1.0 gm. Observations were made immediately before the drug was given and at frequent intervals afterward. All observations were made with the subjects in a basal metabolic state. In addition to measurements of cardiac output, the cardiac size was measured on x-ray photographs made at a distance of two meters. Electrocardiograms were made also,

the heart rate was counted and the blood pressure recorded. Consistent results were obtained from the four subjects studied. With the administration of digitalis to normal men (1) cardiac output *decreased*, (2) the cardiac size *decreased*, (3) the cardiac rate *decreased*, (4) alterations of the T-wave of the electrocardiogram occurred, (5) the blood pressure was usually elevated, (6) the maximum effects were observed 9 to 24 hours after the drug had been given, and had usually passed off at the end of 48 hours.

Effect of Giving Digitalis on the Volume Output of the Heart and its Size in Heart Failure By HAROLD J STEWART (Proc Soc for Exp Biol and Med, 1931, xxi, 209-211)

The methods referred to in the preceding abstract were used in a study of the effect of digitalis on the volume output and size of the heart in heart failure. A small group of patients, among whom were included examples of arteriosclerotic, luetic and rheumatic heart disease, with and without disturbances of rhythm, gave results indicating that in the presence of heart failure (1) the cardiac output diminishes. (2) With the administration of digitalis (a) the cardiac output increases, (b) the cardiac size diminishes, (c) the ventricular rate decreases both when the rhythm is normal and in the presence of auricular fibrillation, (d) and alterations in the form of the T-wave of the electrocardiogram occur. (3) As the effect of digitalis wears off, these functions change in the reverse direction.

Tularemic Leptomeningitis By ARTHUR R BRYANT and EDWIN F HIRSCH (Arch Path, 1931, xii, 917-923)

A chef, aged 48, died on the sixteenth day after lacerating a finger with a rabbit bone while removing pickled rabbit from a jar. At autopsy focal lesions were found in the leptomeninges, contiguous brain tissues, ependyma, subependymal tissues and choroid plexus, which were similar to lesions in the liver, spleen and lungs. All of these had the characteristics of tularemic lesions. In addition there was a diffuse acute exudative meningitis. The serum of the patient, taken

on the fourteenth day, was reported to agglutinate *Bacterium tularensis* in dilutions not greater than 1:40. This low titer is not considered to militate against the diagnosis of tularemia when the serum was taken as early as the fourteenth day from a patient whose failure to form antibodies was indicated by his death two days later. Differentiation from military tuberculosis was made

possible in that suspensions of the crushed lesions killed guinea pigs in five days and produced in them visceral lesions characteristic of tularemia, staining for tubercle bacilli gave only negative results, and lesions of a frankly tuberculous character were not found in the course of a thorough gross and histologic examination of the viscera of the patient.

Reviews

Medical Jurisprudence By CARL SCHEFFEL, Ph B, M D, LL B. xii + 313 pages. P. Blakiston's Son and Company, Inc., Philadelphia, 1931. Price, \$2.50, postpaid.

Contrary to the procedure of most writers on this subject, Scheffel treats of the effect of law upon medical practice and practitioners rather than the reverse. The material presented is of a general character so that the book should be of service to the entire medical profession. There is no attempt to impart highly specialized knowledge applicable only to restricted medical groups. The major divisions of law as they affect the physician are discussed with particular emphasis upon what the author chooses to term "legal prophylaxis", that is, the prevention of unfortunate legal complications involving the medical practitioner. The subjects treated include contractual relationships, law of agency, torts or civil wrongs other than breach of contract, principles of evidence, function of the medical witness, property interests of physicians, criminal responsibility and physicians as law makers. Much of value to the average practitioner is contained in the chapters on contracts and agency. The types of contracts occurring in medical practice, and the specific liabilities of physician and patient in each are well illustrated with specific examples, and many practical suggestions are made to aid in avoiding unnecessary liability. There is included an exposition of various types of commercial contracts which the medical man is especially prone to make, oftentimes unwittingly, herein is timely and practical advice which should be invaluable. The function of the physician

in court is developed at length and an effort is made to show how this relationship affects both the process of justice and the physician himself. The rights of the witness, expert and otherwise, are outlined from the legal point of view, and the importance of an adequate comprehension of the strict meaning of terms commonly used in court is stressed. In general it may be said that the book reflects a legal training rather than a medical one, that it deals with the lawyer's view of the physician rather than with the latter's evaluation of his problems of law and social responsibility. This is particularly evident in the section dealing with autopsies wherein attention is called to a supposed disadvantage of the autopsy because it is thereby frequently shown that the clinical diagnosis was erroneous and that treatment had been applied for a condition that did not exist, thus the liability for malpractice suits may be increased. If such fears were to dominate the medical profession, then progress in scientific medicine would be practically nil. The emphasis on this aspect of the autopsy seems peculiarly ill-advised. Notwithstanding such points which may be called in question, this attitude of mind on the part of the author is in keeping with the purpose of the book and is undoubtedly a large factor in making the work of greater personal value to members of the medical profession than many similar publications. The manuscript is well organized, the argument is logical, the style vivid, only numerous typographical errors and the rather frequent use of a plural pronoun with a singular antecedent mar an otherwise artistically compiled treatise.

Clinical Dietetics A Textbook for Physicians, Students and Dietitians By HARRY GAUSS, M S, M D, F A C P, Instructor in Medicine, University of Colorado, School of Medicine, Assisted by E V GAUSS, B A, Formerly Assistant Dietitian, Presbyterian Hospital, Denver, Colorado 490 pages, 59 illustrations The C V Mosby Co, St Louis, Mo, 1931 Price \$8.00

The needs of three distinct groups, students of dietetics, medical students, and practitioners, were kept in mind as this textbook was being written. Certain difficulties are inherent in the attempt to present the subject matter of use to each of these groups without becoming tiresome to the others. Yet the authors seem to have succeeded to an unusual degree. The first four chapters give a brief but interesting historical outline, a survey of the nature of foods, of dietetic principles, and of the theory of digestion. The latter half of the book is concerned with clinical applications of dietetic principles. A few minor flaws—at least they appear to be such to the reviewer—can be easily remedied in a second edition. It is unfortunate that vitamin E is made to include the pernicious anemia preventing principle, as well as the anti-sterility factor to which this letter should be restricted. Although the fact that both glomeruli and tubules frequently share in nephritis is clearly set forth in the text, the use of Richard Bauer's super-simplified diagram is unfortunate. There are also a number of small but important typographical errors which need correction. The use of historical material is skillfully managed and the introduction of case histories in smaller type adds much to the clinical interest and value. It is encouraging to those who stress in their teaching the importance of constitution, in the sense of Pyle, to find that no less than 16 pages are given over to the significance

A Manual of Clinical Laboratory Methods By CLYDE LOTTRIDGE CUMMER, Ph B, M D, F A C P., formerly Associate Clinical Professor of Clinical Pathology, School of Medicine, Western Reserve University, Cleveland, Instructor in Dermatology and Syphilology, School of Medicine, Western Reserve University, Visiting Dermatologist, Charity and St Alexis Hospitals, Cleveland, Ohio Third Edition, thoroughly revised 585 pages, illustrated with 173 engravings and 12 plates Lea and Febiger, Philadelphia, 1931. Price \$6.75, net

This manual of laboratory methods should be of value to the medical practitioner, as well as to the laboratory technician, because of its style of presentation, which, though concise, gives minute details of even simple procedures. The book consists of twelve chapters, the first five of which deal with the blood, its examination, differential diagnosis of blood dyscrasias, parasitology and bacteriology of the blood, immunology and blood chemistry. An appendix gives an efficient method for examining a large number of urine specimens in a hospital laboratory. This portion of the book also takes up the preparation of normal solutions, the preparation of stains and of autogenous vaccines, as well as other information of interest and value. The last two pages of the book are made up of a Table of Normal Findings, which will be appreciated particularly for the more unusual laboratory procedures. The author presents the newer tests as well as the recent modifications of the standard methods. He describes Kline's Macroscopic Slide Test for syphilis, commenting briefly upon its value. The charts and illustrations are, on the whole, very good and a distinct addition. A bibliography requiring 19 pages gives citations to the original articles in which the technical methods now in vogue were described.

Febiger, Philadelphia, 1931 Price, \$6 50 net

For this second edition of *Hypertension and Nephritis* the entire book had to be reset, so extensive was the revision. The sections on renal acidosis, azotemia with chloride deficiency, the Addis ratio, the pathogenesis of edema, the kidney in diabetes and hemoglobinemia, the role of sensitization in glomerulo-nephritis, renal osteo-dystrophy, the carotid sinus and regulation of blood pressure, cardiac failure in hypertension, and paroxysmal hypertension with suprarenal tumors are either new or have been rewritten. As a result, in this edition the number of pages has been increased by about 50. This is a very complete and satisfactory discussion of the subject, written with the needs of the general practitioner especially in mind. The simpler methods of clinical investigation are stressed and their value emphasized. Throughout management and treatment are set forth in connection with the discussion of each clinical group. This practical clinical application does not mean that the method suffers from lack of scientific analysis, for both morphological pathology and altered physiology are thoroughly presented. Not all pathologists will agree with the elimination of the tubular system from the conception of a defensive nephritis, but approval will be general for the elimination of the term chronic interstitial nephritis, and the firm stand that there is no justification for its use "as commonly applied to those renal diseases which are characterized clinically by arterial hypertension and its consequences."

A Text-Book of Pathology By FRANCIS DELAFIELD, M D, LL D, sometime Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia University, New York City, and T MITCHELL PRUDDEN, M D, LL D, sometime Professor of Pathology, College of Physicians and Surgeons, Columbia University, New York City. Fifteenth edition, revised by FRANCIS CARTER WOOD, M D, Director of the Pathological Department, St Luke's Hospital, New York, Director of the Institute of Cancer Research, Columbia University, New York. 1339 pages, 20 full-page plates, 830 text illustrations. William Wood and Company, New York City, 1931. Price, \$10.00.

No extended review of this well and favorably known textbook is needed. The present edition, the fifteenth, appears after an interval of four years during which time many notable advances in the field of general pathology have been made. Those additions which appear significant and lasting have been added in the revision. The task of including within one book the essentials of both general and special pathology grows more difficult of accomplishment with each succeeding year. Detailed treatment of any one field under such circumstances has become entirely impossible. This well-balanced text continues to be one of the most satisfactory sources for the fundamentals of pathology to be found in the English language. The addition of references to recent reviews directs the reader to more extended information. Many more citations could have been made to advantage.

College News Notes

Acknowledgement is made of the receipt of gifts to the College Library of publications by members, as follows:

Dr Clarence L. Andrews (Fellow), Atlantic City, N. J.—1 book, "How's your blood pressure",

Dr William W. Cadbury (Fellow), Canton, China—5 reprints,

Dr Nathan S. Davis, III (Fellow), Chicago, Ill.—4 reprints,

Dr George H. Lathrope (Fellow), Newark, N. J.—8 reprints,

Thorndike Memorial Laboratory, Boston, Mass.—41 reprints

Dr Henry Daspit (Fellow), New Orleans, Louisiana, Dean of the Graduate School of Medicine of The Tulane University of Louisiana, participated November 23 and 24 in a Medical Institute at Rutherford Hospital, Murfreesboro, Tennessee, presenting papers entitled "Epidemic Encephalitis in General Practice" and "Preventive Medicine Aspects of Psychiatry", and giving a neuro-psychiatric clinic

Dr Harold F. Machlan (Fellow), has been transferred from the U. S. Veterans' Hospital, Lake City, Florida, to become Clinical Director of the U. S. Veterans' Administration Hospital at Indianapolis, Indiana

Dr Roy C. Mitchell (Fellow), Mount Airy, North Carolina, addressed the Grayson-Carroll County Medical Society of

Virginia, November 9, on the subject, "Indigestion After Forty"

Dr Wade W. Oliver (Fellow), Professor of Bacteriology in the Long Island College of Medicine, Brooklyn, N. Y., with his wife, recently returned from an eighteen months' trip around the world. Dr. Oliver was sent by the Rockefeller Foundation as Visiting Professor of Bacteriology and Immunology in the School of Hygiene and Public Health of the University of the Philippines, Manila. He served there during the teaching year of ten months from May, 1930, until March, 1931. The remaining eight months were spent in visiting bacteriological laboratories in, and touring Hawaii, Japan, Korea, China, Bali, Java, Federated Malay States, Siam, Burma, India, north Egypt, Italy, France and Germany

Dr Oliver T. Osborne (Fellow), New Haven, Conn., is the author of an article entitled, "Foods and Health", which appeared in the Illinois Dental Journal for November, 1931. Dr. Osborne is also the author of an article in the Stomatologic Record, New York City, September-October, 1931, entitled "My Viewpoint of Dentistry"

Dr Carl R. Howson (Fellow), of Los Angeles, California, was recently elected President of the Southern California Medical Association. Dr. Harry Henderson (Fellow), Santa Barbara, was elected First Vice President, and Dr. Robert Ramsay (Fellow), Pasadena, was elected Second Vice President. Dr. Fred B. Clarke (Fellow), Long Beach, was the retiring President

Dr H. Beckett Lang (Fellow), was recently appointed Director of Clinical

Psychiatry at the Marcy State Hospital, Marcy, Pennsylvania

Dr. Lang addressed the Fulton Medical Society, October 20, 1931, on "The Mental Hygiene Clinic in the Community" On the same date he also addressed the District Health Officers at Syracuse on "The Malarial Therapy in Neurosyphilis" On November 2, 1931, Dr Lang addressed the Parent Teachers Association of Hamilton, New York, on "Behavior Problems and Their Relation to Mental Illness"

Dr George L. Pinney (Fellow), Hastings, Nebraska, was recently elected Secretary and Treasurer of the Republican Valley Medical Society Dr Pinney recently addressed the Nebraska State School Teachers Association on "Common Sense Pointers on Physical Education"

Dr Clough Turrill Burnett (Fellow), Associate Professor of Medicine at the University of Colorado School of Medicine, delivered addresses at the Colorado State Medical Society in September, 1931, and at the Boulder County Medical Society in Longmont on November 12

Dr George H. Hoxie (Fellow), Kansas City, Missouri, was elected President of the Missouri State Tuberculosis Association at its last meeting in St Joseph, during October Dr Hoxie is Medical Director of the Open Air Schools in Kansas City, as well as of the Kansas City Tuberculosis Society

The following Fellows of the College were on the program of the Tenth Annual Meeting of the Eastern Homeopathic Medical Association held at Trenton, New Jersey, November 4, 5, and 6 Dr Donald R. Ferguson, Philadelphia, Dr E. Roland Snader, Jr., Philadelphia, Dr G. Harlan Wells, Philadelphia, Dr Milton J. Raisbeck, New York, and Dr Linn J. Boyd, New York

Dr Lewis Jefferson Moorman (Fellow), Dean of the University of Oklahoma School of Medicine, Oklahoma City, is the President-Elect of the Southern Medical Association, having been elected at the recent meeting in New Orleans

Dr Frank Smithies (Master), Chicago, was elected President of the American Society of Tropical Medicine at its Twenty-Third Annual Session, held at New Orleans, November 19, 1931

Dr Albert E. Russell (Fellow), of the U S Public Health Service, Washington, D C, delivered an address on Silicosis and Tuberculosis before the Milwaukee Academy of Medicine, Milwaukee, Wisconsin, on November 10, 1931 Dr Russell also read a paper on Occupation and Respiratory Diseases before the Section on Public Health of the Southern Medical Association in New Orleans, November 20, 1931

Dr Karl D. Figley (Fellow), Toledo, Ohio, presented a paper on "Food Allergy" before the Academy of Medicine of Toledo and Lucas County, November 6, 1931

Dr Samuel M. Feinberg (Fellow), Chicago, addressed the Rock Island County (Illinois) Medical Society on "Allergy in General Practice", December 8, 1931

Dr Edgar Mayer (Fellow), Saranac Lake, New York, Associate Professor of Medicine, New York Post-Graduate Medical School and Instructor at the Trudeau School of Tuberculosis, was the guest speaker at a special meeting of the Pacific Physical Therapy Association, held at Los Angeles, December 9, 1931 Dr Mayer's subject was "Are We Abusing our Patients with Light"

Dr Henry M. Moses (Fellow), Brooklyn, New York, addressed the Medical Society of the County of Kings, November 17, 1931, on "Pulmonary Neoplasms—The Clinical Findings and Methods used in Diagnosis"

Dr Franklin B. Bogart (Fellow), Chattanooga, Tennessee, read a paper before the Radiological Section of the Southern Medical Association, at New Orleans, in November, on the subject "X-Ray Examination of the Heart in Left Auricular Enlargement"

Dr Hyman I Goldstein (Associate), Camden, New Jersey, during September and October, 1931, addressed the Krankenkassa physicians in Vienna on "The Physician in American Life To-day—His Position, Socially, Economically, and Scientifically" He spoke on the subject of "Goldstein's Heredo-familial Angiomatosis with Hemorrhages", with lantern demonstration, before the Hungarian Dermatologic Society at Budapest, the Professor Baron A Korányi Medical Clinic, and the Professor Nékám Dermatologic Clinic of the Royal University, both at Budapest, before the German physicians of Carlsbad, Czecho-Slovakia, the American Medical Association, of Vienna, and also before the Professor Morawitz Medical Clinic, Leipzig University, Leipzig, Germany

Dr A L Anderson (Fellow), Springfield, Mo, on November 12, gave a paper before the Southwest Missouri Medical Society on "Metabolimetry as a Measure of Function in the Field of Clinical Medicine"

Dr Chas Hugh Neilson (Fellow), of St Louis spoke on the same program on "Newer Theories of Nephritis", and at the banquet of the Society responded to the toast, "Observation in Medical Education and Medical Practice"

Dr Sidney Alexander Slater (Fellow), Worthington, Minn, addressed the Southwestern Minnesota Medical Society at their semiannual meeting, October 6, 1931, on his recent tour of European clinics

On December 3, Dr Slater addressed the Sioux Valley Medical Society at its annual meeting on the same subject

The Eighty-Fifth Semi-Annual Meeting of the Southern California Medical Association was held in Hollywood, November 13 and 14, 1931, under the presidency of Dr Fred B Clarke (Fellow), Long Beach, Calif Other Fellows of the College who held offices were

Dr. William H Barrow, San Diego, Calif—First Vice President,

Dr Carl R Howson, Los Angeles, Calif—Secretary-Treasurer

At the above meeting, Dr. Ross Moore (Fellow), Los Angeles, delivered a paper

on "A Concept of Toxic Activity—Therapeutic Application", and Dr Samuel Ayres, Jr (Fellow), Los Angeles, in conjunction with Dr Nelson P Anderson, delivered an address on "The Use of the Patch Test in the Diagnosis of Contact Dermatitis"

Dr Clarence L Andrews (Fellow), Atlantic City, N J, was elected President of the Atlantic County (N J) Medical Society, December 11, 1931

Dr Arthur C Morgan (Fellow), Philadelphia, addressed the annual meeting of the Sixth District Branch of the Medical Society of the State of New York, at Waverly, N Y, September 22, 1931, on the subject "The Treatment of Acute Cardiac Tragedies".

Dr Fred H Voss (Fellow), Kingston, N Y, has been elected a member of the New York Academy of Medicine

On November 10, 1931, Dr George A Merrill (Fellow), Brooklyn, N Y, addressed the Bay Ridge Medical Society on the subject "Allergy and its Common Manifestations"

Dr. Ray M Balyeat (Fellow), Oklahoma City, Okla, Associate Professor of Medicine, University of Oklahoma Medical School, addressed The Medical and Surgical Association of the Southwest, at Phoenix, Arizona, December 4th on "History Taking and Etiology in Headaches Due to Specific Hypersensitiveness"

Dr Balyeat recently has been elected President of the Oklahoma City Clinical Society

At the Louisiana Follow-Up of the White House Conference on Child Health and Protection, November 12-14, at Baton Rouge, Dr Ellen C Potter (Fellow), Trenton, N J, conducted a round table on the "Functions of Government in Public Welfare", and addressed the general assembly on the responsibility of government in that field

In New Orleans, La, November 15-16, Dr Potter delivered addresses before the Branch of the Medical Women's National

Association and before the City Officials and Private Social Agencies concerning the "Interdependence of Public and Private Social Work"

Dr Potter addressed the Annual Convention of the New Jersey Organization for Public Health Nursing at Trenton, December 4, on "The Responsibility of Board Members" The same day, Dr Potter also addressed the State Conference of Social Work of New Jersey on "Community Organization for Social Work"

The Second District Branch of the Medical Society of the State of New York held its Twenty-fifth Annual Meeting at the St George Hotel, Brooklyn, November 19, 1931 Dr Henry M Moses (Fellow), Brooklyn, delivered an address on "Supportive Treatment of Pneumonia", Dr Albert F R Andresen (Fellow) and Dr Simon R Blattes (Fellow), both of Brooklyn, delivered addresses on "Health Examination from the Standpoint of Gastro-enterology" and "Health Examination from the Standpoint of Internal Medicine", respectively

Dr Joseph H Barach (Fellow), Pittsburgh, Pa, addressed the Westmoreland County Medical Society, November meeting at Mount Pleasant, Pa, on "Treatment of Pneumonia"

Dr Robert A Knox and Dr George W Ramsey (Fellows), Washington, Pa, presented a case of Niemann-Pick's disease before the Pittsburgh Pediatric Society, October 23 This case will be described in a paper which has been accepted for a future number of the ANNALS

Dr Fred M Meixner (Fellow), Peoria, Ill, is the author of an article on "Chest Injuries as the Cause of Heart Lesions" in the December issue of the Illinois Medical Journal

Dr M Murray Peshkin (Fellow), New York City, addressed the Hackensack Hospital Staff Association, Hackensack, N J, Dec 15, 1931, on "Allergy in Children"

OBITUARIES

DR EDWARD TYLER EDGERLY

Dr Edward Tyler Edgerly, Fellow of the College since March 10, 1925, died in Rochester, Minn, on November 15, 1931, following an operation for vesical calculus, at the age of sixty-seven years

Doctor Edgerly was born in Ottumwa, Iowa, January 15, 1864 After attending the Ottumwa public schools he graduated from Phillips Exeter Academy and received his A B degree at Harvard University in 1885 He graduated in medicine from Northwestern University Medical School in 1889 In the competitive intern examination for Cook County Hospital, Chicago, he received the highest grade and became chief of the resident intern

staff After completion of his intern service, he was appointed an instructor in medicine and physical diagnosis of his Alma Mater

In 1894, while on a tour of European medical centers accompanied by his father, Mr J W Edgerly, the latter died suddenly in Paris, and this unfortunate occurrence changed the course of Doctor Edgerly's career In the interest of the family fortunes, Doctor Edgerly made the willing sacrifice of a promising medical future in Chicago and devoted his services to the business interests of the family until 1908, when he returned to his old love and began the active practice of medicine in his home city His fine training and high mental endowments

soon brought him into leadership among the physicians of his state

In 1902 he was commissioned First Lieutenant in the Medical Reserve Corps, U. S. Army, and entered active service at the beginning of the World War. He served as Captain and Major, and Chief of the Medical Service of the Base Hospital at Camp Dodge during the period of the War. During Major Edgerly's service at Camp Dodge his conduct of the epidemics of meningitis and influenza received official commendation.

He was a member of the Wapello County and Iowa State Medical Societies, the Iowa Clinical Medical Society (past president), and the American Medical Association. He was an active member of the Iowa Tuberculosis and the Iowa Heart Associations.

Doctor Edgerly was married in 1891 to Miss Nettie Thurston of Chicago, who with a son, John T. Edgerly, and a daughter, Mrs. Nelson Rupe, and four grandchildren survive.

Since his affiliation with the College he has been an active worker in promoting its interests in every way and a faithful attendant at the annual meetings. During the Boston session in 1929 the members of his Harvard class (L. A. '85) arranged a dinner in his honor, and it was the writer's privilege to be present as a guest. Among those attending the dinner were Mr. Roland W. Boyden, eminent authority on international law and later successor to Justice Charles H. Hughes on the Court at the Hague; his brother, Mr. Wm. W. Boyden, a leading member of the Chicago Bar; Dr. Horace D. Arnold of Boston, a president of one of the leading life insur-

ance companies, and others prominent in the professions and public affairs. Greetings were read from Dr. W. S. Thayer of Baltimore, and Associate Justice Edward T. Sanford of the U. S. Supreme Court. The late Dr. Lawrence Litchfield of Pittsburgh was also a member of this class.

Doctor Edgerly distinctly contributed to the progress of scientific medicine during his period, and the impression of his fine and genial personality, generous nature, and high professional ideals will linger with us while memory lasts.

(Furnished by Walter L. Bierring, M.D., F.A.C.P., Des Moines, Iowa)

DR. JOHN FRANCIS WALLACE MEAGHER

Dr. John Francis Wallace Meagher (Fellow), Brooklyn, New York, died August 25, 1931, of injuries received when a concrete pillar supporting an observation platform on which he was standing collapsed. He was fifty-one years old and in the prime of health and vigor.

Dr. Meagher was born in Brooklyn, March 22, 1880. He was graduated from the Boys High School of Brooklyn and from the College of Physicians and Surgeons of Columbia University in 1901. He was an intern at St. Mary's Hospital, Brooklyn, from 1901 to 1902. In 1903 he made a special study of nervous and mental diseases at St. Lawrence State Hospital, Ogdensburg, New York, and later at the Manhattan State Hospital for the Insane at Ward's Island, New York. Thereafter he was associated in this work at the Bellevue Psychopathic Ward and in the Neurological Insti-

tute During the World War he served in the rank of major At first he was stationed at Camp Mills, Mineola, and later at Kelly Field, San Antonio He was sent overseas and worked at Base Hospital 37, Dartford, Kent, and after that at Base Hospital 216 at Savenay, France After the war was over he remained in the service in the capacity of psychiatrist at the Army Hospital at Plattsburg, New York, and was discharged in 1919

At the time of his death, Dr Meagher was Consultant Psychiatrist at Kings Park State Hospital and Neurologist at St Mary's, Mary Immaculate, and Rockaway Beach Hospitals

Dr Meagher was a frequent contributor to medical literature and was associate editor of the Medico-Legal Journal and associate editor of the Journal of Urology and Cutaneous Diseases His special interest, however, was in the legal and criminal aspects of mental abnormalities and diseases For many years he had been a consultant alienist in the office of the District Attorney of Brooklyn, where his talents and abilities, along his special lines, were recognized as invaluable to the solution of their problems

He was a member of the Pi Lambda Phi and the Chi Zeta Chi Fraternities He was a member of the American Medical Association, New York Academy of Medicine, Neurological Society of New York, Neurological Society of Brooklyn, American Psychiatric Association, Medical Society of the County of Kings, and the Society of Medical Jurisprudence He was also a member of the Crescent

Athletic Club and the Cavalry Club of Brooklyn He became a Fellow of the American College of Physicians in 1920

(Furnished by Luther F Warren, M D, F A C P, Governor of Eastern New York)

DR LAWRENCE EVANS CHAPMAN

Dr Lawrence Evans Chapman (Internal Medicine) was born August 28, 1887, at Georgetown, Texas, received his M D degree from the University of Texas, School of Medicine, 1915, and became a member of the Galveston County Medical Society, the South Texas District Medical Society, State Medical Association of Texas, Southern Medical Association and American Medical Association He was elected a Fellow of the American College of Physicians, March 4, 1928 At the time of his death Dr Chapman was Associate Professor of Clinical Medicine at the University of Texas School of Medicine, and a visiting physician on the staff of the John Sealy Hospital He died suddenly, October 21, of coronary thrombosis

Dr Chapman was a man of the highest principles, of the utmost devotion to the teaching and practice of Internal Medicine, and a most excellent type of gentleman His death came as a great loss to the Medical Department of the University of Texas, with which he had been associated in various positions since 1915 He first became associated with the faculty as Instructor in Physiology, which position he held until 1917 After his training in Physiology, he became connected with the Chair of Practice of

Medicine where he continued until his death, passing through successive and rapid promotions from Instructor to the rank of Associate Professor

(Furnished by C T Stone, M D ,
F A C P , Governor for Texas)

DR THOMPSON FRAZER

Dr Thompson Frazer (Fellow), Newark, New Jersey, died suddenly October 9, 1931, of cerebral hemorrhage, aged fifty-four years

Dr Frazer was born in Buffalo, New York, September 10, 1877 He attended the Newark Academy of Newark, New Jersey, and later Princeton University, from which he received the degree of B S in 1897, and M S in 1904 He received his medical training at the College of Physi-

cians and Surgeons at Columbia University, receiving his medical degree in 1901

Dr Frazer practised medicine in Asheville, North Carolina, for some time, later removing to Newark, New Jersey, where he established himself Among his appointments was that of Visiting Physician, St Barnabas Hospital He was a member of his county and state societies, Southern Medical Association, The American Heart Association, American Climatological and Clinical Association, and a Fellow of the American Medical Association He was elected an Associate of the American College of Physicians on March 13, 1925, and his credentials for Fellowship were accepted on December 30, 1926

Multiple Arterial Occlusions*

By HAROLD W. DANA, M.D., F.A.C.P., *Boston, Mass.*

FOR many years we have been cautioned, with regard to the use of quinidine in the treatment of auricular fibrillation, of the possible danger that we might cause the extrusion into the circulation, when the previously dilated auricles should contract, of thrombi formed in these inactive chambers of the heart. Such an accident would seem not only to be possible, but even to be likely, should any method of treatment be successful in re-establishing rhythmic contraction of auricles long inactive, and undoubtedly this misfortune does at times follow the use of this drug, although much less frequently than one would expect upon theoretical grounds.

Outside of the cinchona group, no drug is known to have an effect on auricular contraction. Digitalis, though widely used in fibrillation, is employed only as a means of setting up a barrier against ventricular overstimulation. Mackenzie¹ in speaking of the danger from the use of digitalis in fibrillation, was referring only to the possibility of producing too great a degree of block after the pulse rate had become sufficiently slow. Hare² refers to the possible dangers of massive doses of digitalis in patients with a tendency to embolism "arising in all probability from the valvular disease",

apparently quite apart from any discussion of the effect of this drug in fibrillation.

In this paper I should like to present the hypothesis that pituitrin, either alone or in conjunction with adrenalin or digitalis, may be capable of causing the stationary auricles to contract rhythmically. The evidence is based upon the apparent effect of one or more of these drugs in causing what I believe to have been multiple embolism, with the simultaneous disappearance of a pre-existing fibrillation of the auricles. The patient in whom this occurred was, on this particular admission to hospital, under treatment for lobar pneumonia, and after having been digitalized, she had received repeated subcutaneous injections of pituitrin because of circulatory failure as evidenced by falling systolic and pulse pressures. She had also received one or more injections of adrenalin during one, at least, of the two severe chills with partial collapse following each of two large intravenous injections of glucose. There was no evidence of an endocarditis. No quinine had been used in treatment.

The effect of pituitary extract upon unstriated muscle, in the uterus, the intestine, and the blood vessels, is long established, within recent years

*Submitted for publication, June 9, 1931

several observers^{3,4} have noted the emptying of the gall bladder as the result of the action of this agent, and since cardiac muscle is closely related to unstriated involuntary muscle, it would seem at least theoretically possible to obtain some contractile influence upon the heart from pituitrin, which Dale⁵ believes does in fact occur. Twenty years ago, however, Wiggers,⁶ in a series of experiments both on the perfused heart and by intravenous injection, found that pituitrin did not cause any increase in the amplitude of cardiac contraction. More recent experimenters, as Ross with others⁷, Kolls and Geiling⁸, Geiling and Resnik⁹, speak of the possibility of direct action of the extract on heart muscle, or of indirect action through coronary constriction, though rather in causing dilatation than increased contraction.

It would seem that the only possible explanations for what occurred in the patient referred to, are as follows

(1) that the fibrillation was due to the pneumonia and disappeared when the patient's condition improved,

(2) that there was a spontaneous cessation of a paroxysmal fibrillation, and

- (a) that emboli were thereby extruded into the circulation, or
- (b) that thromboses occurred in various locations, also spontaneously, or
- (c) that the thromboses were due to the effect of pituitrin locally in causing narrow-

ing of the capillary bed in the extremities,

(3) that both the return to normal auricular rhythm and the occurrence of embolism were due either to pituitrin or to its effect combined with that of other drugs. Whether such possible effect of pituitrin might have been through stimulating the contraction of the auricles or through its depressant effect upon cardiac muscle, or by stimulation of the cardio-inhibitory center, will not be discussed.

Why glucose injections, when given in pneumonia, should produce, at times, a condition simulating anaphylactic shock, has not as yet been satisfactorily explained. It is possible that such a reaction may be due to massive destruction of leucocytes with the production of toxic substances. That either glucose shock or the single injection of adrenalin used in its treatment could have caused thrombosis in this case does not seem likely, since there was an interval of six days between the last use of these agents and the appearance of any arterial occlusion.

That fibrillation may have resulted from the pneumonia has no particular bearing, since there had been undoubted previous attacks of fibrillation. In fact, there is no actual proof that a spontaneous termination of fibrillation did not occur in this case. While the patient had had "palpitation of the heart" for eight or ten years and definite symptoms of cardiac decompensation for three years, when admitted to hospital one year ago with a diagnosis of auricular fibrillation, the heart action was reported as regular in all examinations during her three

weeks' stay, and no fibrillation was diagnosed at that time. However, no electrocardiographic examination was then made, for some reason, so that fibrillation with regular ventricular action cannot be positively excluded.

If, during the patient's latest stay in hospital, there had been a spontaneous restoration to normal rhythm, then the fibrillation can be assumed to have been paroxysmal in type, of short duration, unlikely to have produced clot formation and extrusion of emboli.

With regard to the possibility that there could have been a spontaneous re-initiation of auricular dynamic contraction, with an almost simultaneous onset of widely scattered thrombus formation due to the local action of pituitrin upon the blood vessels, there are the following difficulties to be ex-

plained. In the first place, this requires belief in a most remarkable coincidence, further, the vessels involved in the hands and feet were not merely capillaries, but vessels of good size, again, the first evidence of the process occurred in the tip of the nose, then in both feet, next in the right hand, later on the left forearm, probably in the lungs, and finally on one cheek, this distribution of lesions being spread over several days, and as a final argument, the process in the cheek seemed rather definitely embolic in that there was pus formation.

Unfortunately, the evidence in the case is not at all complete, for various reasons, chiefly mechanical, no electrocardiogram was taken until after the heart action had become regular, and eight days after the first evidence

FIG 1 Photograph of right hand, taken Feb 15th, 1931, showing condition of fingers at the time of discharge from hospital

of interference with peripheral circulation. Further, while it is the impression of several of us that the return to normal rhythm occurred at the same time that onset of gangrene of the extremities appeared, this cannot be substantiated from the hospital records.

Very much to the point is the observation of Halsey¹⁰ in Barker's Endocrinology. Rénon and Delille are quoted by Halsey as stating that arrhythmias were not influenced by pituitrin, but that in several cases tachycardia was controlled after other therapy had failed, and to this Halsey makes the commentary, "Every clinician of sufficient experience is aware of the difficulty of determining whether the cessation of one of these

paroxysms following any line of treatment is an instance of *post hoc* or *propter hoc*. However, there is pharmacological evidence that the injection of extracts of this gland may directly depress cardiac muscle and in this way it is possible that such would exert a favorable influence in tachycardia."

Resnik and Geiling¹¹ made an electrocardiographic study of the action of pituitary extract and showed changes in the heart rate, partly due to stimulation of the cardio-inhibitory centre and partly to a "muscular action". It is possible that the low amplitude of all waves in the earliest electrocardiogram from the case here reported is due to the depressant action of pituitrin, rather than to any specific action in making the auricles contract

FIG 2 Gangrene of tip of second left toe at the time of discharge from hospital. Two months before, all toes of both feet were black and appeared gangrenous.

FIG 3 Electrocardiogram, Nov 28, 1930 Normal sinus rhythm Rate 94 Q R S = 0.06 second T flat in all leads Left ventricular predominance Auricular premature beats in leads I and II Low amplitude (maximum 2.5 mm)

FIG 4 Electrocardiogram, Dec 30, 1930 Auricular fibrillation—rate approximately 115 Q R S = 0.08 second T biphasic in all leads Left ventricular predominance

with beginning gangrene of all the digits of right hand, and "splinter hemorrhages" under all the finger nails of left hand. On the 25th there were discolorations of both feet and it is noted that the dorsalis pedis pulsation was felt on the right foot but not on the left, with no impulse at external or internal malleoli of either foot and no popliteal pulsation in either leg. At this time there was a purple area on the right forearm. One day later, two pustules appeared on the right cheek and these developed in 24 hours into an abscess of the upper lip and right side of the face, which was opened. By this time the lungs were clear. All toes of both feet were black all over and apparently gangrenous. By Dec 1st, there was a sharp line of demarcation across metacarpophalangeal joints of all fingers of the right hand.

On Nov 28th, the first electrocardiogram showed a normal sinus rhythm, with auricular premature beats. On Dec 21st, the patient started again to fibrillate. Digitalis, which had been stopped for about a month, was resumed and the heart action became regular for a few days. An electrocardiogram on the 30th showed fibrillation, as also on Jan 3rd, 1931, and although on Jan 5th there was normal sinus rhythm, this did not

continue. Accordingly, after careful trial, the patient was put on quinidine on Jan 7th, and all electrocardiograms taken later, on Jan 15th and Feb 3rd, showed normal rhythm. There was no clinical evidence of fibrillation after January 8th.

At the time of leaving the hospital, the condition of the nose and cheek had completely cleared up, all of the toes had healed with the exception of the terminal joint of the second left toe, while circulation had returned in a considerable part of the fingers and thumb of the right hand.

When discharged on March 1st, 1931, the patient felt better than she had for three years or more.

SUMMARY

1 The case is reported of a patient in whom multiple arterial occlusions occurred coincident with the disappearance of auricular fibrillation.

2 It is believed that the return to normal auricular rhythm was related to the use of pituitrin.

3 It is believed that pituitrin should be used cautiously in the treatment of patients with auricular fibrillation.

Hereditary Deforming Chondrodysplasia*

By M A SPANGELBERGER, M D , F A C P , *Denver, Colo*

HEREDITARY deforming chondrodysplasia is a comparatively uncommon disease of the skeletal system, characterized by bony deformities caused by multiple cartilaginous exostoses and enchondromata (bone cysts) Ehrenfried¹, in 1915, collected over 600 cases from the entire medical literature of the world; Stocks², in 1925, brought this number up to 765 Ray³, in 1930, found 156 cases reported in the American literature and added one of his own Since then Hyndman⁴ has published an interesting case report The most recently reported case is one by Blount⁵ in which a mild rachitis was coincident This case, with our own, brings the total number of American cases to 160

Heredity was noted in 83 per cent of the cases reviewed by Ehrenfried, in 75 per cent by Ray and in similar percentages by other authors, however, there remains the minority percentage in which a history of heredity cannot be demonstrated The fundamental etiological factors are still undetermined No satisfactory treatment has been discovered

The exact status of this disorder can be determined only by a larger series of authentic cases and the following case is herewith reported

HISTORY OF PATIENT

Walter W, age 11, of German descent and a native of Missouri, was the first born of three children For six months he was breast fed, then the mother, becoming aware of existing pregnancy, weaned him Several cow's milk formulae were tried Thereafter a diet of strained vegetables, grain gruels, and the lighter cereals was given The child began to creep at nine months, and walked before the end of the year Development proceeded without untoward incident until three and one-half years of age At this time knoblike excrescences were noted in close relation to the joints of the extremities These appeared simultaneously, showing most prominently about the knee joints Locomotion became difficult, and normal movements of the wrist and elbow became limited

A pediatricist was consulted who made a diagnosis of rickets and prescribed a diet rich in calcium Cod liver oil was also given, but no improvement followed Since walking was impossible, a brace was applied, consisting of a belt with metal braces extending along each side of the legs, fastened to soles of specially made shoes This, too, was unsatisfactory and the child continued resting part of the time in bed and part of the time making his way around with unsteady gait and crawling when balance was lost At the age of five, improvement ensued The ability to walk returned weight increased, and the child entered school at six Since that time he has been active, taking part in play as a normal child While he has sustained many falls, there has never been a fracture

The boy came under observation again, not for the disorder herein described but as the result of a survey of all grade

*Submitted for publication, July 13, 1931

school children for faulty breathing. His parents were advised that he required a tonsillectomy. The only other illnesses were pertussis, measles, and mumps at the respective ages of four, six, and eight years. Recovery in each was complete and uneventful.

At the time of the tonsillectomy, a bony spur from the outer condyle of the femur was excised, and a cyst on the anterior aspect of the tibia was curetted.

Father's History The father was 37 years old, white, of German descent, a native of Missouri, and the eldest of nine children. He was reared on a farm and followed agricultural pursuits until 29 years of age. His height was 6 ft. 4 in, weight 224 lbs, of powerful physique. He had never had severe illness or injury. Minute examination of the skeletal system showed not the slightest disorder. The usual laboratory tests, including Wassermann, were negative.

Mother's History The mother was the second of five children, age 35 years, a native of Missouri, and of German descent. She married at 19 and gave birth to this child one year later. Two other children were born 11 months and three years later. She was reared in the country and had the usual childhood diseases with uneventful recoveries. Her health was excellent until five years preceding examination when pulmonary tuberculosis developed. A change of residence was advised, and the family then came to Colorado. Her disease became quiescent and was arrested at the end of two years. At that time she had regained her normal weight of 130 pounds and was apparently in a fair state of health, when a Graves' syndrome began with a rather sudden onset. Thyroidectomy was done and after several months apparent recovery was established. Physical examination now shows a cavitation in the upper right lung, but no signs of activity. Basal metabolic rate is minus two. Usual laboratory tests including Wassermann, negative. As in the instance of the father, a careful examination of the osseous system disclosed no abnormality.

Correspondence with relatives of both parents fails to elicit evidence of any gross

abnormality such as exostoses. Nor is there any report as to unusually short stature or limitation of joint movements.

Physical Examination of Child The patient is a fairly well nourished boy, height 48 inches, weight, 68 pounds. As he stands nude (figures 1 and 2) misshapen joints are strikingly apparent. Knoblike protuberances, of varying size occur at the elbows, wrists, knees, ankles and about the chest and pelvis. These are larger about the joints of the left side of the body. *Manu valgum* and *genu valgum* exist, and these, too, are more marked on the left side. There is a varying amount of limitation of movements in all major joints, he is unable to flex the left thigh on body, pronation and supination of the left hand cannot be fully accomplished. The gait is awkward, but the patient is remarkably agile, despite the disadvantage of distorted joints.

Head The head is symmetrical, the face proportionate, and no exostoses are evident. The hair is fine and abundant, with clean scalp. The skin is warm, smooth, of excellent texture and color.

Eyes Blue, pupils round, equal, react to light and accommodation. A diopter of myopia is measured in each eye. There exists no muscular imbalance. The fundi are normal.

Ears Normal.

Teeth Of good structure, well spaced, and dentition has progressed normally for age.

Throat The tonsils are hypertrophic, exhibiting crypts containing caseous material. A pad of adenoid tissue is visible in the posterior-pharynx.

Thorax The thorax is flattened, but respiration is adequate and equal. There are no adventitious sounds on auscultation of the lungs.

Heart Normal outline of the heart is found on percussion. The apex is in the fifth interspace, one-half inch within the nipple line. The heart tones are normal. There is a brief presystolic murmur at the apex.

Abdomen The abdomen is flat, soft, and no organs or masses are palpated.

Nervous system All superficial and deep reflexes react normally.

FIG 1

FIG 2

FIGS 1 and 2 Anterior and posterior views of patient to show skeletal deformities

Skeletal System The findings are based upon physical examination and a complete x-ray examination of the entire skeleton

Skull There are no exostoses, enchondromata or deformities in the bones of the skull and face

Spine The spine is straight Nearly all the transverse processes are involved

Ribs There is an exostosis on the left fifth rib, near the spine, with some pressure deformity of the fourth rib above this exostosis A larger growth can be felt and seen on the seventh rib in the right mid-axillary line There are also several smaller deformities on the anterior ends of several ribs

Pectoral Girdle There are several exostoses along the superior margin of the scapulae and the glenoid fossa is involved The acromial end of each clavicle is broadened and irregular

Pelvic Girdle There are several exostoses on each ilium The acetabulum on both sides is broadened and shallow The texture of the pelvic bones is coarser than normal

Upper Extremities The humerus on both sides is broadened at the upper end and the shaft of the bone is bowed outward The bones of the forearm on both sides are shortened and bowed, the ends broadened and distorted and there are large exostoses at the lower ends These deformities are most marked on the left side and have resulted in dislocation of the upper end of the radius Carpals, metacarpals and phalanges show abnormal variations in shape and size Several exostoses and enchondromata are noted (Figure 3)

Lower Extremities The neck of each femur is markedly straightened and broadened The trochanters are widened and thickened The texture of the upper end of the shaft is abnormally coarse The lower ends are broad and thick, the contour is irregular and there are several clubbed stalactite growths pointing away from the epiphyses The upper end of each tibia shows the same characteristic stalactite exostoses as described for the femur The upper end of the fibula is broadened and thickened, almost twice normal size, irregular in contour and a large irregular osteoid for-

mation is noted on the posterior surface (Figure 4) The lower end of the diaphysis of the left fibula is expanded to three times normal diameter by a large enchondroma, a similar deformity, not quite so marked, is noted on the lower end of the right tibia The bones of the feet show about the same degree of pathological change as the bones of the hands

Laboratory Examinations Hemoglobin, Dare, 92 per cent, red cells, 4,100,000, white cells, 5600, Wassermann test negative Several estimations of blood calcium gave values within normal limits Urine acid, sp gr, 1.020, sugar, bile, acetone, and indican tests were negative No pus cells, red cells or casts were seen, and crystalline deposits were normal The test for Bence-Jones' protein was negative

DISCUSSION

Since the various features of this disorder have been thoroughly discussed in many papers we shall consider only those which have a direct bearing on this case

The physical findings establish the diagnosis The short stature, the shortening of the extremities with deformities at the elbows, knees, wrists, and ankles, the inability to extend the forearms fully, the multiple palpable and, in part, visible exostoses near the ends of the long bones are characteristic The roentgenograms show many enchondromata and many spurs, arising chiefly from the metaphyses near the epiphyseal junctions The x-ray pictures of the enchondromata have the soap bubble appearance of a benign giant cell tumor In giant cell tumor exostoses do not develop, the disease is progressive, accompanied by much pain, and eventually results in fracture, extension by spontaneous perforation or surgical interference Simple, non-hereditary

osteomata, chondromata and enchondromata are usually single. According to Honeij⁶ the bones in chondrodysplasia are very sensitive to trauma and easily respond by formation of exostoses. Osteitis fibrosis cystica does not produce the exostoses and the curettings of a cyst determine the diagnosis.

The case under discussion was diagnosed by several consultants as rickets. This diagnosis seems plausible in view of the history of feeding by the mother until she was five months pregnant. Roentgenograms at

this time might possibly have determined the correct diagnosis.

Hyndman⁴ gives a very satisfactory differential diagnosis between chondrodysplasia and chondrodystrophia fetalis. He rightly points out that the latter is a generalized disease usually involving all the epiphyses equally and producing a symmetrically dwarfing skeletal deformity which is usually well developed at birth and therefore dates back to intrauterine life.

Although true heredity and familial incidence in this disease has been unquestionably demonstrated by many

FIG 3 X-ray of forearms. Note shortening and bowing, and exostoses and enchondromata.

FIG 4 X-ray of knee joints Note enchondromata and stalactite exostoses

authors, a careful search into the family history of the patient revealed no other cases. However, a hereditary history is often lacking, as in this case. Possibly the stigmata of this disease may at times be so insignificant that they would be overlooked except on the most careful physical examination, including a complete x-ray examination of the skeletal system. It may also be that those cases in which actually no hereditary basis exists can not be considered as true examples of this disease, even though the physical findings are typical. Ehrenfried¹ coined the name "hereditary deforming chondrodysplasia", other authors have used other names because they did not

agree with his conception of the major features. It may finally be that the hereditary factor is not found in some disturbance of the bone anlage, but in some disturbance of the endocrine system. In that case the changes in the skeleton may appear only in certain cases of such endocrine disturbance. In our case there is a history of very severe exophthalmic goiter during the pregnancy of the mother. Jegat⁷ suggests that tuberculosis may have an etiological significance. Although there is a history in this case of tuberculosis in the mother, the evidence for such a conclusion is unconvincing. The importance of heredity in this disease has been established be-

FIG 5 Cross section of exostosis from left femur. Note disorderly growth of cartilage and bone.

yond all reasonable doubt But is it not possible that the hereditary factor is to be found in an underlying disturbance of the endocrine system?

Whatever the real cause may be it results in a chaotic growth of the metaphyseal-epiphyseal line The deformities resulting may in part be due, as Keith⁸ has suggested, to a failure of proper pruning of the ends of the long bones and for this reason he calls this disease "diaphysial aclasis"

Microscopically, the picture presented is one of disorderly cartilaginous growth with irregular ossification as shown in figure 5, a cross section of an exostosis, and in figure 6, curettings from an enchondroma in the lower end of the femur These sections correspond to the pathologic changes so beautifully described by Ehrenfried¹ and Honeij⁶

Symptomatology in this disease depends upon interference by the deformity with motion, blood and nerve supply, upon secondary changes such as inflammation and upon true tumor formation Hyndman⁴ believes that all cases of hereditary deforming chondrodysplasia should be carefully checked from time to time to detect immediately any possible true neoplastic changes If such occur he advises prompt and complete surgical excision

Sulphur, phosphorus, calcium, and magnesium determinations in the blood and the urine have so far not given any clew as to rational treatment in this disease Certainly calcium therapy does not produce the beneficial effects that it does in rickets If the disease is a true hereditary disease determined in the bony anlage perhaps no satis-

FIG 6 Curetting from enchondroma of left tibia Note atypical cartilage and abnormal bony growth

factory treatment will ever be discovered

SUMMARY

A case of hereditary deforming chondrodysplasia is reported.

No evidence of hereditary origin could be discovered

There was a history of exophthalmic goiter and of tuberculosis in the mother

The Dietetic Control of Some Forms of Hypertension and the Associated Gastrointestinal and Nervous Symptoms*

By V C ROWLAND, M D , F A C P , *Cleveland, Ohio*

IT IS extraordinary, in view of the available facts, that the profession has so largely ignored the therapeutic possibilities of diet and weight control in certain forms of hypertension associated with plethora and gastrointestinal and nervous symptoms

By way of introduction, a brief reference to the literature of hypertension will be of interest

From the time of George Johnson in 1868, and of Gull and Sutton in 1872, the subject of vascular disease has been continuously studied, and approached mainly from the pathological viewpoint. After much controversy as to the characteristic changes in the intima and media, there seems to be fairly general agreement with the views of Fischer and Schlayer in 1910, and of Brogsitter in 1924, and of Kernohan, Murphy and Grill in 1930, namely, that the primary change is an hypermyotrophy of the media or at least a thickening of the arterial muscle wall with an increased number of nuclei which may be interpreted as a hypertonic contraction in response to some hypothetic pressor substance, or

some stimulus to the sympathetic nerves. The thickening of the muscular layer of the vessels is not necessarily associated with any primary degenerative change. Later there may be proliferation of the intima and subsequent hyaline or other degeneration. Kernohan, Anderson, and Keith, in 1930, reported an extensive study of hypertension from biopsies from muscular tissue showing a similar thickening of the muscular layer. Ophthalmoscopic evidence, such as that of Volhard in 1931, also seems to confirm the idea of a primary contraction and only subsequent degenerative change.

There have also been a few disconcerting cases of essential hypertension with death by cerebral or other accident, with absolutely negative pathological findings. These cases, together with much clinical evidence, suggest the conception of Clifford Allbutt, that there is a functional stage of hypertension, and that the characteristic pathology of diffuse vascular disease is the result rather than the cause, contrary to current pathological opinion. Furthermore, it is generally agreed that there is no sharp classification of the different forms of hypertension that they differ mainly in degree, that

*Given before the American Gastro-Enterological Association at Atlantic City, May 4, 1931

either benign or malignant hypertension may run a progressive course with very moderate elevation of blood pressure, and that much advanced vascular sclerosis may have no elevation of blood pressure whatever

The literature of obesity also is important as a background to the following report upon the dietetic management of some forms of hypertension. Insurance statistics, largely ignored by the medical profession, have for years repeatedly confirmed the association of increased blood pressure and high mortality rates with obesity. The Actuarial Society of America, in 1925, published a compilation of the results of the statistics of twenty-six companies, and a similar forthcoming compilation of a larger and better controlled set of statistics, it is said, will confirm, that approximately two-thirds of all individuals over forty years of age, who are ten pounds or more overweight, show a definite elevation of blood pressure. Similar figures were shown in private studies of obesity, such as that of a thousand cases in Boston by Preble in 1923. There is some statistical evidence, also largely ignored, of the lowering of blood pressure by reduction in weight.

Furthermore, the literature of the more scientific type on the subject tends to the idea that obesity is largely exogenous (Newburgh). Students agree, as Bauman states, that there is no inherent change in the basal metabolic rate, except in the subthyroid group. The work of Grafe and others points to a compensatory rise in the basal metabolism during periods of overfeeding. Increased metabolism implies increased blood pressure and

pulse rate. There is, of course, a type of obesity with low blood pressure and low metabolism. However, as Evans has recently shown, if basal metabolism rates are calculated on normal rates for the height and age of obese individuals, instead of actual weights, many of these rates will be high instead of low, and thyroid medication clinically unsatisfactory, as might be expected. There is evidence pointing to a lower specific dynamic action to protein in certain obese individuals. This is not constant, however, and can only be one factor in the obesity, possibly due to deficiency of anterior pituitary function (Liebesing).

The type of patient who presents the form of blood pressure most amenable to dietetic control is one in his forties or early fifties, definitely overweight, ruddy, strong, and active, eating heartily of rich food, not too fond of muscular exercise, and not too highly nervous. He is usually seen in private practice in the so-called higher social levels, although in our country and generation, even in hard times, high caloric food, if not wholesome balanced diet, is freely available and obesity abounds well down the social scale. The patient is either symptom free or beginning to show minor nervous and digestive symptoms such as palpitation, headache, heartburn, and flatulent indigestion. Frequently he has gained twenty or thirty or more pounds over his optimum weight at twenty-five or thirty years of age. He may complain of lack of initiative or slight lack of endurance in comparison with his earlier working capacity. If his blood pressure had been observed, there was considerable fluctuation with

a general tendency toward a higher and more continuous blood pressure level. Frequently, but not invariably, there is a family history of the apoplectic habitus and high blood pressure or of obesity and diabetes. The most suitable cases show no organic pathology or very early signs of cardiac enlargement and aortic fullness fluoroscopically. Presumably, the hypertension is due to a functional arterial hypertonus or that with an early and often controllable stage of diffuse vascular disease. Our ideal patient is intermediate between the young individual with very high systolic and diastolic pressure and the older patient with advanced arteriosclerosis or marked kidney pathology.

As indicated below, a reducing regimen in this group of cases effects a very prompt reduction in blood pressure and by maintaining weight at or near a normal level, permits of sustained control of the blood pressure to a degree not generally appreciated. There is, apparently, also a functional moiety in the hypertension associated with advanced cardiovascular disease which may be gradually reduced to the optimum level as determined by the increased peripheral resistance. For purposes of practical therapy, therefore, the most useful classification, if not the clearest in the present confusion of the subject, is that of functional hypertonus and fixed hypertension of organic peripheral obstruction.

With this introduction, we may approach the following observations upon the relationship between diet, weight, hypertension, and associated symptoms.

From personally kept records of

private patients over a period of years, one hundred cases were selected for this study. All blood pressure observations were made personally by the writer under the same conditions. In the tabulation, part of which appears below, the first weight given is the weight of the patient at the beginning of management, the second is the patient's statement of weight in early adult life in health, usually about twenty-five years of age, as a guide to normal weight, the third is the weight at the end of a period of management, mainly by diet. This was a balanced diet of milk, egg, meat, vegetable, and fruit, simply low in sweets, fats, pure starches and total calories. Huchard's idea that the quality of food stuffs is more important than the quantity has never been supported. However, excess of protein was avoided in our diets. Salt restriction played no part, although seasoning, condiments and stimulants were interdicted during the period of management. Frequently a prompt drop of five or ten pounds is noted the first week. Later, however, one pound a week was the goal. In all cases, reduction was kept at a rate which gave an improved sense of well being, not weakness or distress. The beginner was often hungry with the sudden change in his habits of eating. In fact gastric analysis in a few cases showed hypersecretion and hyperacidity in comparison with readings taken after there had been time for adjustment to the reduced diet. Clinically too, after this adjustment, many patients testified that they no longer had the craving for excessive food intake. A minimum of medication was used, usually a little bromide or luminal for

short periods for symptomatic relief. Thyroid extract likewise was used only occasionally and in small dosage. No nitrites, sulphocyanates, calcium, atropine, bismuth salts, or other drugs were used in the reported cases. None of the cases recorded were taken off their usual schedule of work. Associated conditions were noted such as indigestion, ulcer, gall bladder disease, dia-

betes, thyroid disorders, menopause, cardiovascular disease, nervous disturbances, urticaria and other eruptions, focal infection, arthritis, etc

A sample of the method of tabulation of data follows together with individual and composite graphs of weight, systolic and diastolic pressure, and, in diabetes, of blood sugar

TABLE I

From the family histories, it is very apparent that heredity plays a definite rôle in the individual tendency to hypertension and also to obesity, but instead of accepting this as inexorable, efforts at prevention are shown to be very definitely worth while. As in

diabetes, also with an hereditary predisposition, the latent tendency need not always become manifest. On the contrary, when carbohydrate metabolism is impaired full control allows improved function. Ten cases of diabetes are listed among the hyperten-

CHART 1, Patient 28. A woman of 51 years with an initial weight of 200 lbs, blood pressure 200/98, blood sugar reading of 240 mg, and sugar in the urine. Under dietetic management and observation for one year, final readings were weight, 166, blood pressure, 138/80, blood sugar, 90. Relief from weakness, dyspnea and palpitation.

sion cases and the hypertension curve nearly parallels the hyperglycemic curve

Typical cases of weight reduction with prompt response in blood pressure are shown graphically. The range in total weight reduction was 0 pounds to 54 pounds and in systolic blood pressure from 10 mm of mercury to 105 mm. The average weight loss for the 100 cases was 20.06 pounds. The average drop in systolic pressure was 40.85 mm, in diastolic pressure, 17.32 mm. The average period of management was 8.28 months.

Many of these cases were seen at long intervals for years afterwards with blood pressures controlled in proportion to their weight control. Preliminary to this report (April, 1930) a group was rechecked. The following is an example.

Case 10, a woman seen in 1924, with a blood pressure of 210/110 and weight of 190, now shows a pressure of 120/80 and weight of 157, at 57 years of age. She has entirely and very intelligently changed her habits of eating, has lost all craving for rich desserts and heavy eating, but has continued at her same occupation during the whole period of seven years.

CHART 2, Patient 9. A woman of 69 with initial weight, 190, blood pressure, 210/110. First year of management reduced weight to 155 and blood pressure to 140/82. Relief from severe neuralgias and "rheumatism."

It is recognized that some error occurs in certain cases in that the first readings may be high on account of nervousness and acute upsets which suggest their seeking medical advice at the time. At best there are fluctuations which must be averaged over a period of time. With care, however, this error can be fairly well discounted and with observation over a long pe-

riod, the reaction of a given patient to strain, to the menopause, and to acute infections can be noted and the blood pressure compared with the original reading. In the cases reported, no factor was as important as that of weight. After full adjustment at the reduced weight levels, the blood pressure was much more constant even under extra strain.

CHART 3, Patient 50. A woman of 49 with initial weight 160, blood pressure, 215/110. First year of management reduced weight to 140 and blood pressure to 130/78. Relief from weakness and indigestion.

Case 41, for example, is a teacher of 58, seen first in vacation time, July, 1930, symptom free at the time although she had had much neuralgic pain. She did not appear to be much overweight at 138 pounds but she was eating heartily and her early adult weight was 115 pounds. Under management she very gradually reduced to 123 with blood pressure reduction of 170/90 to 125/75 which remained quite constant during the following teaching year, the last observation being on April 18, 1931.

Relapses with marked increase in weight as in case 56 (shown in the graphic record) show the direct effect of increased weight on blood pressure after a prolonged pe-

riod of control. Relapses are not so common as might be expected, especially among intelligent people under intelligent and conscientious supervision and with proper regard for normal balance and variety in diet.

ASSOCIATED SYMPTOMS

Nervous and digestive symptoms most commonly accompany the hypertension. Of the former, headache, neuralgias, paresthesias, vasomotor instability, palpitation, insomnia, nervous irritability to the point of a definite psychosis, all have occurred and

CHART 4, Patient 56. A man of 62, initial weight of 190, blood pressure 220/40. Reduced in 4 months to 155 pounds and blood pressure of 160/100. Relapse for 2 years, gaining weight to 176 with pressure of 220/100. Maintained for 6 months at 160 to 155 pounds with pressure 145 to 160/100.

have been relieved to an extraordinary degree

Digestive symptoms range from simple distress, pyrosis, eructations, flatulence, nausea and vomiting to a frank gallbladder type of dyspepsia or ulcer syndrome. An analysis of the histories showed seven per cent of clinical diagnoses of gall bladder disease, three confirmed by operation, and four similar diagnoses of ulcer, none of which were confirmed by operation. It is quite probable that more cases had had at some time during their history definite peptic ulcer, since the symptoms were often highly suggestive. X-ray studies were not made in cases that responded promptly to dietetic management of the hypertension. This suggests caution and individualization in the treatment of ulcer so that the older ulcer patient with a tendency to weight and hypertension is not eventually hurt more than helped by frequent high fat feedings such as the full Sippy diet.

Furthermore, there occurs as a complication of hypertensive cardiovascular disease a very intractable form of ulcer with deep craters and rapid erosion leading to hemorrhage or perforation. Autopsies often show these lesions associated with advanced circulatory pathology. Sometimes the ulcer seems to be of the nature of a terminal complication. Accordingly, whatever aggravates the hypertension and circulatory strain, such as a high caloric diet, would be a bad form of ulcer treatment.

Healed ulcer cases who gain unduly in weight often show symptoms suggestive of recurrence. That one can make this diagnosis too hastily is shown

by a case in which the writer had an unusual opportunity due to the accidental death of the patient of showing a scaphoid cicatricial fossa in the duodenum with no hint of recent ulceration or inflammation. Deformity of the duodenum had been apparent by x-ray shortly before death, similar to that observed several years before following treatment for typical symptoms and profuse hemorrhage. His recent symptoms were apparently due to heavy eating *per se*. The case is instructive as suggesting that the ulcer syndrome even in a former ulcer patient may precede actual ulceration, and that the latter is but an incident in, or a complication of, a primary metabolic, or other disorder.

Gallbladder disease with its relation to the cholesterol metabolism and its frequent association with the overfed type of patient is even more closely related to hypertension. Likewise very suggestive symptoms may result from the metabolic disorder *per se* without organic disease demonstrable even at autopsy. Many of these symptoms are relieved by the reducing management. In the above 100 cases, there were 26 cases with chronic indigestion of varying degree besides the 7 diagnosed as definite gall stones or gallbladder disease. At least 22 of the 26 were satisfactorily relieved.

The gastroenterologist has a great therapeutic opportunity in the simple dietetic management of these cases. The incidence of hypertension and excessive weight is enormous and apparently increasing in our generation. Janeway found 111 per cent of 7872 cases in private practice with blood pressures above 165. Deaths from

hypertension and its complications in the United States are said to number 140,000 annually. Diet has gotten into disrepute because of the many weird abuses under that name, but will undoubtedly play a larger rôle in health supervision in the future. With the new emphasis on preventive medicine, now arrived at the stage of individual participation, we may expect the matter of diet to be brought more in line with medical science.

SUMMARY

1. The literature of essential hypertension indicates that the primary structural change is an hypermyotrophy of the media of the arterioles and that degenerative changes are secondary. Functional hypertonus occurs, in rare cases without demonstrable

pathology even at autopsy. A hypothetical pressor substance of metabolic or glandular origin is postulated as the causative agent.

2. The literature of obesity shows an unmistakable association with hypertension. Approximately 66 per cent of all people over 40 years of age and 10 pounds or more over weight show hypertension.

Obesity is largely exogenous.

Metabolic rates are usually normal, sometimes increased.

Mortality rates are increased in proportion to the excess in weight.

3. Heredity is a strong predisposing factor in hypertension and obesity as in diabetes and other diseases.

4. A balanced reducing diet intelligently supervised is the largest single

CHART 5 Graph of averages in 100 private patients personally observed at weekly to monthly intervals. Initial weight, 166.83 pounds. Reduced to 134.20 pounds over an average of 8.28 months. Pressure reduced from 175.05/96.28 to 134.20/78.96.

factor in the control of certain types of hypertension and the associated symptoms. It is more efficacious and more practicable than is generally appreciated.

5 One hundred private patients personally observed, many for long periods, showed the following average figures

Initial weight	166.83 pounds
Initial systolic pressure	175.05 mm Hg
Initial diastolic pressure	96.28 mm Hg
Period of observation	8.28 months
Age	53.7 years

Reduction in weight	20.06 pounds
Reduction in systolic pressure	40.85 mm Hg
Reduction in diastolic pressure	17.32 mm Hg

6 In indigestion, gallbladder disease, and peptic ulcer, after middle life and especially with the tendency to hypertension, high caloric diets should be avoided.

7 Weight control after middle life presents one of the largest opportunities for personal prophylaxis and may be carried out in connection with the periodic health examination.

An Evaluation of Stool Vaccines in Chronic Irritable Colon Therapy*†

By JOHN G. MATEER, M.D., F.A.C.P., and JAMES I. BALTZ, M.D.,
Detroit, Michigan

THERE are several conceptions regarding the etiology of the condition variously designated as chronic irritable colon, neurogenic mucous colitis, chronic non-ulcerative colitis, or mucous colopathy. Barker¹, Bockus², Jordan³, Lichty⁴, and the writer⁵, have emphasized the importance of neurogenic factors in aggravating irritable colon symptoms, and the need for their control in any adequate program of therapy. Dorst and Morris⁶ have recently emphasized the theory that chronic irritable colon is probably an allergic state, due to absorption of the foreign protein of certain stool bacteria. Others have contended that this condition is essentially a chronic infection, involving the wall of the colon, and that the term colitis can be properly applied, therefore, to this large group of cases.

Satisfactory therapeutic results can be obtained in a number of these cases from the employment of a comprehensive program, including the control of various neurogenic factors, bland diet, physiological regulation of the bowels,

antispasmodics, and in some instances, changing the stool flora with lactodextrin and acidophilous milk. Certain obstinate cases, however, are resistant to the above types of treatment, and present an important therapeutic problem. Because of this fact, mainly, and also in view of the lack of agreement regarding the underlying etiology, it has seemed worthwhile to evaluate the practical effectiveness of vaccine therapy in these cases, and also to study the validity of the allergic theory. An abundance of material has been available, and it has therefore been possible to conduct our work upon a selected group of obstinate, irritable colon cases.

Only those autogenous stool vaccines were used, which produced definite, specific skin reactions with intradermal tests. Obviously this does not mean necessarily that the therapeutic results obtained were specific in character, viz., due to a direct effect of the vaccine upon the underlying etiological factor. *A priori*, the possibility of a non-specific mechanism, with a general, systemic effect, must be recognized.

METHOD AND ITS EVOLUTION

Warm stool specimens were cultured and vaccines prepared which con-

*Read before the American Gastro-Enterological Association, Atlantic City, May 5th, 1931.

†From the Gastro-Intestinal Division of Medical Department, Henry Ford Hospital.

tained originally one and one-half billion organisms per cubic centimeter. The vaccines were prepared according to the method of Hartman⁷ and Jackson. In the more *recent* therapeutic experience with detoxified vaccines, detoxification has been carried out by subjecting viable, rather than heat killed, suspensions of the various strains to a concentration of one per cent purified and tested sodium ricinoleate for fifteen hours. The organisms were washed, then, several times with normal saline, to eliminate the sodium ricinoleate, and its irritating effect. Finally, trikresol (0.4 per cent) was added, as a preservative, and to provide sterilization.

Vaccine skin tests were carried out in *all* cases with *unaltered vaccine*, not subjected to sodium ricinoleate, and 1/20 c.c. of each vaccine was injected intradermally. These injections were made upon the flexor aspect of the forearm in all male patients, and upon the extensor surface of the thigh in female patients. The skin reactions were noted twenty-four hours later, as this seemed to be the optimum interval. The patients showing skin sensitivity were then started on vaccine injections of the one or more organisms to which they had reacted.

As a rule the first therapeutic dose of vaccine consisted of a total dose of one minim, containing the one or more organisms indicated, and injected subcutaneously. Subsequent injections were given at intervals of three to seven days, depending upon the degree of transient reaction of the patient to the last injection. In the earlier experience, the dose was increased about two minims each time.

Since this increase, with a vaccine to which the patient was hypersensitive, led to a certain number of disagreeable reactions, it has been the custom for some months to increase the dosage not more than one minim per injection. Furthermore, if a patient had any appreciable reaction to this increase, the same dose was administered as was given at the previous injection, or a smaller dose. A course of treatments consisted of six to ten injections, with an average number of eight. The maximum dosage, therefore, consisted of eight minims. In some cases the dose could not be increased beyond two or three minims because of reactions. In fact, certain of the more sensitive patients were overwhelmed with the reaction following one minim of this concentrated vaccine.

More recently, therefore, more dilute vaccines have been prepared which contain from twenty-five to fifty million organisms per cubic centimeter. In some very sensitive individuals it has been necessary to provide further dilutions, even as low as ten thousand organisms per cubic centimeter, or less in occasional instances, before the vaccine was tolerated. In most cases, the symptomatic improvement is then definite. A longer course of vaccine injections, with very gradual increase of dosage, is given to these individuals. On the other hand, in those cases with greater tolerance for vaccine, better therapeutic results are often obtained when a somewhat more concentrated vaccine is used, provided the patient does not receive sufficient vaccine to produce a temporary reaction. The dosage should be adapted to the individual. If over-dosage is

avoided, a four-day interval between injections is very satisfactory. A shorter interval is tolerated by some patients. It is difficult to determine the most effective duration of the course of injections, and the desirability or practical necessity of attempting to obtain complete skin desensitization.

Until recently the unaltered vaccine has been used rather than vaccine detoxified with sodium ricinoleate, according to the recommendation of Dorst⁶ and Larson⁸. The more recent experience with detoxified vaccine injected intramuscularly, is already sufficiently under way to indicate advantages. The resulting avoidance or diminution of temporary reactions seems to offer a distinct advantage, both from the standpoint of the patient's comfort, and from that of the therapeutic results obtained, this modification supplementing the effect of reducing the dosage. Certain patients have not tolerated the unaltered vaccine, but have been relieved greatly following treatment with the detoxified preparation.

Dorst's work was limited by giving vaccine therapy alone to a group of patients with chronic irritable colon,

who had received no other type of treatment. It has not seemed justifiable in this work to withhold from these patients the older, comprehensive, therapeutic measures of recognized value, mentioned above. It is common knowledge that the majority of mild and moderate cases of irritable colon will become symptom-free with this program of therapy alone, provided sufficient care is taken in the elimination of the nervous factors.

In order to put vaccine therapy to a more severe test, and to eliminate favorable results not related to this type of treatment, we have utilized a carefully selected group of sixty-eight patients with chronic irritable colon, who had resisted the older therapeutic measures with definite persistence of symptoms. Vaccine therapy, of the type noted above, was introduced then as the only new therapeutic measure, other conditions remaining essentially constant. The practical results of such vaccine therapy upon colon distress, pylorospasm, and the associated symptoms are tabulated statistically in table I. The sixty-eight cases shown in this table have been treated with concentrated and unaltered vaccine. This

TABLE I
Practical Therapeutic Results of Autogenous Stool Vaccine
Injections Upon Symptoms of 68 Cases*

	Colon pain	Pylorospasm syndrome	Constipation	Headache	Vertigo
Number of cases	57	29	34	23	11
Symptoms aggravated	2 (3%)	1 (3%)	0	2 (9%)	0
Symptoms unchanged	9 (16%)	8 (28%)	8 (24%)	8 (35%)	5 (46%)
Slight improvement	8 (14%)	3 (10%)	4 (12%)	1 (4%)	2 (18%)
Moderate improvement	11 (19%)	2 (7%)	4 (12%)	2 (9%)	0
Marked improvement	9 (16%)	2 (7%)	5 (14%)	4 (17%)	1 (9%)
Complete relief	18 (31%)	13 (45%)	13 (38%)	6 (26%)	3 (27%)
Total cases improved	46 (81%)	20 (69%)	26 (76%)	13 (56%)	6 (54%)

*Cases with persistence of symptoms after other therapy, showing results following introduction of vaccine therapy as the only new therapeutic measure. (Undiluted and unaltered vaccine was used in this group of cases.)

provides statistical data for comparison with the results obtained from diluted and detoxified preparations

In the majority of obstinate cases thus treated, the pylorospasm and colon symptoms either improved or disappeared. Included in this group were a few unusually marked cases of pylorospasm, unassociated with colon distress, in which the symptoms had persisted in spite of comprehensive and intensive treatment. Yet these symptoms not infrequently disappeared in a striking manner with the introduction of vaccine therapy. Many of these cases noted marked improvement in their constipation, and were able to discontinue supplementary measures for the relief of this symptom, after vaccine treatment had been instituted. Certain patients, not listed in table I, but presenting a well established diarrhea as the main evidence of colon irritability, were also promptly relieved with vaccine. There were certain patients who had experienced for a long time very distressing headaches of the type often associated with constipation and gastrointestinal distress, not relieved by any of the previous therapeutic measures instituted, but which disappeared under vaccine therapy.

In this connection, it is admitted that in general the objective study of functional symptoms is difficult, and the danger of undervaluating psychological influence is recognized. How-

ever, this group of obstinate cases, whose symptoms had not responded satisfactorily to the previous therapeutic measures, did not represent an enthusiastic group, susceptible to therapeutic suggestion. Furthermore, symptoms as persistent as irritable colon or pylorospasm pain, or chronic headaches, are so stamped upon the individual as to be independent of any mental suggestion. A definite improvement or disappearance of such symptoms is therefore significant.

On the other hand, the symptoms referred to in table II are more purely subjective and less convincing as an index of the effectiveness of vaccine therapy. Even an objective change such as gain in weight is quite dependent upon improvement of appetite. Nevertheless, it was interesting to note that many of these patients, who had complained of chronic fatigability, were enthusiastic about their general improvement, and emphasized particularly the fact that they felt more energetic.

As to the average duration of symptomatic improvement, the above cases have been followed from one to twelve months. This period has been of sufficient duration to demonstrate the practical value of vaccine therapy.

Although vaccine therapy has proved very helpful in the majority of the more obstinate cases with irritable colon and related symptoms, there is evidence that it does not minimize the

TABLE II
Other Results of Vaccine Therapy in Group of 68 Cases

- 1 Appetite improved in 39 patients (57%)
- 2 Gain in weight in 11 patients (16%) (In these patients who gained weight, the average gain per patient was eleven pounds, and occurred with no change in dietary advice as previously outlined)
- 3 Improvement in general feeling of well being occurred in 46 patients (68%) (Improvement very striking in some cases)

therapeutic value or importance of the comprehensive therapeutic program, effective previously in the treatment of the majority of the mild and moderate cases. A major nervous problem which could not be controlled satisfactorily was an outstanding factor in some of the cases, whose gastrointestinal distress and pain were not relieved by vaccine therapy. In certain other cases, whose symptoms were relieved only partially by vaccine treatment, it was found that changing the stool flora was an extremely helpful supplementary measure. The importance of substituting a *diluted* vaccine, in those cases not relieved by a more concentrated preparation, has been emphasized.

Table III summarizes the frequency and degree of skin reaction occurring, with vaccines prepared from different stool organisms, in the total group of patients presenting chronic irritable colon and associated symptoms, upon whom skin tests were carried out. This group of 198 patients included the 68 treated with vaccine and referred to above, and 130 additional patients. The colon bacillus vaccine gave the most marked areas of skin reaction, although there was frequently

marked skin sensitivity to the non-hemolytic streptococcus. Skin sensitivity was less frequent, and usually less marked, when present, with the other organisms isolated. A number of patients were definitely skin sensitive to two or more organisms. The largest areas of skin reaction occurred with the *communior* strain of *B. coli*. In some cases, areas as large as nine or ten centimeters in diameter were seen, with associated injection of the lymphatic vessels leading to the axilla. In Table III the average intensity of the skin reaction, as evidenced by redness and swelling, has been measured on the scale of one to four plus for the various organisms.

In a sub-group of these cases, skin tests were done, both with these autogenous vaccines, and also with the corresponding strain of vaccines, originally prepared from stool cultures in other cases. It was found that the skin reactions in the majority of cases were similar with the autogenous and non-autogenous stool vaccines of the same organism. For example, with the two strains of colon bacillus, 98.5 per cent of the patients giving a positive skin test with the autogenous vaccine also gave a positive reaction with the

TABLE III

Frequency of Isolation from Stools, and Vaccine Skin Sensitiveness, of Common Stool Organisms (in 198 Patients Presenting Symptoms of Irritable Colon, Pylorospasm or Both)

	Frequency of isolation from stool (cases)	Frequency of positive skin reaction when isolated (cases)	Average diameter and intensity of positive skin reactions		
<i>B. Coli (communis)</i>	279 (91%)	170 (95%)	4.4 X 4.4 cm	+	+
<i>B. Coli (communior)</i>	77 (38%)	74 (96%)	4.5 X 4.5 cm	+	+
<i>Streptococcus nonhemolytic</i>	107 (54%)	67 (62%)	2.7 X 2.7 cm	+	+
<i>Staphylococcus aureus</i>	27 (14%)	13 (49%)	2.4 X 2.4 cm	+	+
<i>Streptococcus viridans</i>	11 (5%)	4 (36%)	2.8 X 2.8 cm	+	+
<i>Hemolytic streptococcus</i>	2 (1%)	0			

corresponding nonautogenous preparation. In the case of the nonhemolytic streptococcus stool vaccines, the discrepancy between the skin reactions of autogenous and nonautogenous preparations was considerably greater than with the colon bacillus. This fact may be due to the great variety of strains of the streptococcus. There were occasional cases in which the nonautogenous vaccine gave a positive skin test, and the autogenous vaccine of similar strain produced a negative test.

A control group was carefully selected, which included twenty-one healthy individuals, with no present or past history of symptoms of irritable colon, pylorospasm, or any of the common allergic conditions. In comparing the findings in table IV with those of table III, it is noted that the frequency and degree of positive skin reactions are appreciably less in the control group than in the irritable colon cases. This is particularly true of the three common stool organisms, viz., the two strains of colon bacillus and the nonhemolytic streptococcus. The more infrequent stool organisms are probably chance findings. Their significance may lie in the fact that they come from the mouth, throat or gall

tract. In this control group, positive skin tests occurred almost as frequently in the children as in the adults. The five children included were between five and fourteen years of age.

In table V the degree of skin reaction before, and two weeks after, completion of vaccine therapy was compared in a group of sixteen consecutive cases. It is noted that there was a definite tendency for the skin reaction to decrease in diameter and intensity. A decrease was noted in 75 per cent of the cases, including 12.5 per cent which exhibited a complete disappearance of the skin sensitivity, following vaccine treatment. As to the possibility of parallelism between symptomatic improvement and decrease of skin reaction following vaccine treatment, no final deductions can be drawn from this small group of sixteen cases. In the majority of cases there was some parallelism, but the significance of this finding was rendered questionable by the fact that, in one case, the skin reaction increased after vaccine, although there was marked symptomatic improvement, and, in a second case, there was a similar degree of symptomatic relief, with no change in the degree of skin

†Some skin sensitivity was still present after vaccine therapy in 87½% of cases

sensitivity This experience is not surprising, however, in view of the existing knowledge regarding marked changes in degree of skin sensitivity, which occur occasionally in various types of allergy, without any treatment having been administered

In almost every instance where vaccine therapy is used with good effect, the question is raised as to whether one is dealing with a specific effect, or with a nonspecific protein reaction This attitude is due mainly to the excellent work of Peterson⁹, Joseph L. Miller¹⁰, and others, who have demonstrated the occurrence of nonspecific protein therapy, its value in various conditions, and the importance of con-

trolling any work that appears to show specific vaccine effects

As regards the nature of the therapeutic action of autogenous stool vaccine treatment in irritable colon and pylorospasm patients, the evidence favoring a specific effect is

1 That there is a marked skin reaction to certain of the isolated stool bacteria in a very high percentage of this irritable colon group of patients,

2 That the best therapeutic results in relieving irritable colon pain seem to occur when systemic reactions are avoided, by using small, rather than large, doses, and by giving the detoxified vaccine, whereas Miller¹⁰ and others have emphasized the im-

portance of obtaining a systemic reaction, preferably with some fever, if satisfactory results are to be obtained from a nonspecific type of therapy

On the other hand, the main point of evidence suggesting a nonspecific protein mechanism is that an appreciable percentage of the *control* group shows skin sensitivity to the common stool organisms. For example, 69 per cent of this group were skin sensitive to the *B. coli communior* vaccine, when this organism was isolated

When one considers the fact that the human race is exposed universally and throughout life to most intimate contact with, and absorption of, disintegrating stool organisms, it is not surprising that an appreciable percentage of the control group was skin sensitive to stool vaccines. It is also a well recognized fact that there are individuals who have never had hay fever symptoms, who, nevertheless, show skin sensitivity to ragweed. This fact, in itself, is not supportive of either specificity or nonspecificity. When the real mechanism of allergy and immunity is discovered, questions of this sort will be answered more definitely

Recently we have started to treat a control group of irritable colon patients with nonspecific, milk protein injections, as a further check upon the exact mechanism underlying the above therapeutic results in irritable colon cases, but this work is too recent to discuss results at the present time. We are also studying a group of irritable colon patients from the standpoint of their skin sensitivity to various other substances, in an effort to further elucidate the problem

SUMMARY

1 Autogenous, stool vaccine therapy, utilizing organisms to which the patient is skin sensitive, has been employed in the treatment of a group of patients with obstinate irritable colon and associated symptoms. In order to put vaccine therapy to a more severe test, and to eliminate favorable results not related to vaccine treatment, a carefully selected group of sixty-eight patients has been utilized, who had resisted previously a comprehensive program of the older therapeutic measures with definite persistence of symptoms. Vaccine therapy was then introduced as the only new therapeutic measure, other conditions remaining essentially constant

2 The most important fact revealed in the above observations has been the demonstration of the definite therapeutic value of properly selected stool vaccines, in partially or completely relieving the remaining symptoms of the majority of these more obstinate irritable colon patients. The above experience has demonstrated that vaccine therapy not only tends to relieve the colon distress and associated symptoms, but also makes it possible for a majority of these patients to tolerate a greater variety of diet and a greater degree of nervous activity, and furthermore, to place less emphasis upon the supplementary measures for the control of constipation

3 The therapeutic results tabulated statistically in table I were obtained with concentrated and unaltered vaccine, giving an average course of eight injections. The results obtained more recently, with a longer course of more dilute vaccines detoxified with sodium

ricinoleate, and with greater emphasis upon determining the optimum dosage for each individual, have been even more satisfactory than those outlined in table I, and obtained with the original method. The exact statistics with the newer method have not yet been compiled; but certain patients who failed to tolerate the concentrated, unaltered vaccine have obtained symptomatic relief from the more recent method

4 Vaccine therapy *should not displace* the older therapeutic measures of recognized value in irritable colon cases, such as control of various neurogenic factors, proper diet and regulation of bowels, the discriminate use of antispasmodics, and, in some cases, the changing of stool flora. This comprehensive program, with special attention to correction of all faulty habits, should precede vaccine therapy for the following reasons

(A) The symptoms of the majority of the mild and moderate cases will disappear with this comprehensive therapy. Vaccine therapy is not necessary, therefore, in this group

(B) In the obstinate cases, whose symptoms do *not disappear* with the comprehensive program, the colon irritability and spasm, nevertheless, tend to be *partially* reduced by the elimination of aggravating neurogenic factors and other faulty habits. If vaccine therapy is introduced subsequently, as a supplementary measure, the

end results of colon therapy, as well as the general condition of this group of patients, will be more satisfactory than if the comprehensive therapy were to be omitted, and vaccine therapy alone utilized. As the effects of vaccine therapy become apparent, those measures in the comprehensive program which are rendered unnecessary should be discontinued.

5 The colon bacillus was the most frequently isolated organism, and, as a vaccine, gave the most frequently positive and most marked skin reactions. (See table III)

6 Skin sensitivity in a *control* group of healthy, asymptomatic individuals, with no history of any irritable colon or allergic symptoms, was tested. (See table IV) Sixty-five per cent of the control group showed skin sensitivity to one strain of the colon bacillus, and sixty-nine per cent to another strain

7 Skin sensitivity to stool vaccines was shown to decrease and even to disappear, in some irritable colon cases, under vaccine therapy. (See table V)

8 As to the exact mechanism involved in the production of the above therapeutic results of vaccine therapy, evidence is presented for and against a specific vaccine effect. The available evidence does not justify a definite decision upon this question. A control group of patients is being treated with nonspecific milk-protein injections

On the Advantages of Being Ill

“TO BE ill, or to undergo an operation, is to be initiated into the mystery of nursing, and to learn the comforts and discomforts of an invalid's life, the unearthly fragrance of tea at daybreak, the disappointment of rice pudding when you thought it was going to be orange-jelly, and the behavior of each constituent part of the bedclothes You know, henceforth, how many hours are in a sleepless night, and what unclean fancies will not let us alone when we are ill, and how illness may blunt anxiety and fear, so that the patient is dull, but not unhappy or worried, and how we cling to life, not from terror of death, nor with any clear desire for the remainder of life, but by nature, not by logic In brief, you learn from your own case many facts which are not in text-books and lectures, and your patients, in the years to come, will say that they prefer you to the other doctor, because you seem to understand exactly how they feel I wish you therefore, young man, early in your career, a serious illness, or an operation, or both For thus, and thus alone, may you complete your medical education, and crown your learning with the pure gold of experience The crown of experience is like the crown of Lombardy, a band of iron set in a band of gold and it is believed, even now, by some people, that the iron of that crown is more valuable than the gold”—From *Confessio Medici*, by STEPHEN PAGET, F R C S (The Macmillan Company, New York City, 1931, Reissue)

Diagnostic Value of Secretory Function in Gastric Disease: Various Methods Studied and Compared*†

By ERNEST H. GAITHER, M.D., F.A.C.P., *Baltimore, Md*

DURING the past few years, renewed and continued interest has been manifested by numerous investigators in the domain of gastric secretion, and the test which has apparently met with almost universal favor has been that in which histamine, subcutaneously administered, has been used as the stimulator of gastric gland activity.

A careful survey of the current literature on this subject reveals the interesting fact that practically all observers agree as to the direct action of this drug upon the gastric glands, or upon a mechanism which has intimately to do with their secretion, innumerable tests of acidity have satisfied many workers in this field that a study of the acid values by means of the histamine test, will enable one to form an excellent and reliable idea as to the ability of the glands to secrete acid, and will furnish information of true diagnostic worth.

Immediately after the successful application of the histamine test for acid

determination, certain investigators entered upon a searching inquiry into the matter of enzymes, chlorides, and other constituents, and, as was to be expected, conflicting claims, either hostile or extravagantly favorable in nature, were made as to the dependability and diagnostic value of the test in the presence of disease under varying conditions. Because of these conflicting and unsatisfactory views, it was decided to confine the present investigations to a consideration of acid values only.

The proponents of the histamine test state that its advantages are not only the subcutaneous application which eliminates the disturbing psychic factor induced by the mastication of solids and the swallowing of liquids as in other test meals; but also the fact that the dosage may be standardized and pure juice obtained. Then, too, because of the direct action of this substance on the gastric glands, many cases which show achylia by other test meals will give an acid response after the injection of histamine.

Objections to the Ewald, alcohol, and various other test meals, have been presented by some observers, who claim that contamination and dilution

*Read before the American Gastro-Enterological Association, Atlantic City, May 5, 1931.

†From the Gastro-Intestinal Clinic of Johns Hopkins Hospital, Baltimore.

of the gastric content are so engendered by the introduction of these substances, as to mask the true secretory power of the gastric glands, they aver, also, that the neutralization of the hydrochloric acid by saliva, food, and regurgitation of duodenal contents further complicates an already deceptive result. The contention is advanced that tests other than the histamine injection do not provide sufficient stimulation to obtain an adequate response from the gastric glands.

I am unable to accept these objections as valid, some of them would appear to be mere sophistry. For instance, it can certainly be proven that in the majority of cases, bread and water supply an adequate stimulation to gastric gland secretion, and as for the argument regarding neutralization by swallowed saliva and regurgitation of duodenal contents, as well as that concerning contamination brought about by solids and liquids, does not such a process more nearly simulate the usual physiologic routine of digestion? And after all, are we not endeavoring to ascertain the functional capacity of the gastric glands under conditions as nearly physiologic as possible? No one can gainsay the fact that Nature never depends upon histamine injections to bring about a normal response of the gastric secretory glands.

This study represents an investigation by three methods, using the fractional extraction

I THE ALCOHOL TEST MEAL

Technique Patient given fifty c c of an 18 per cent alcohol solution containing 0.005 gm phenolphthalein

II EWALD MEAL

Technique One slice of white bread without butter, and one glassful of cool water, ingested forty-five minutes before extraction

III HISTAMINE TEST

Technique Dissolve one histamine tablet of 0.005 gm in three c c distilled water, multiply the weight of the patient by 0.005, this gives the number of c c of histamine solution to be administered subcutaneously

In estimating acidities we made use of the accepted figures of twenty to forty degrees for free hydrochloric acid, and forty to sixty degrees for total acidity, as indicating normal limits, realizing that the acidities following histamine stimulation are considerably higher.

This would seem the opportune moment for stressing two important points, first, in selecting this series of cases for research, every available method of investigation was brought into use in order to insure the absolute correctness of each diagnosis, second, we were not prejudiced for or against any of the methods, and were eager to consider all evidence and all established facts judicially and in order, so as to reach if possible, a correct and unbiassed conclusion as to the diagnostic value possessed by any of the methods.

The cases were grouped under the following headings

- 1 Achylia gastrica
- 2 Adhesions (postoperative, plastic gastric operations)
- 3 Colitis
- 4 Gastric neurosis

5. Hepato-biliary pathology (cholecystitis; cholelithiasis)

6 Ptosis and atony

7 Peptic ulcer

ACHYLIA GASTRICA

We charted in this group all those cases showing in any of the tests a lack of free hydrochloric acid, and have included all such cases from the various groups. There were nineteen in this group

8 Achylia by all three tests

6 Achylia by alcohol, normal or hypochlorhydria by histamine and Ewald

3 Achylia by alcohol and Ewald, normal or hypochlorhydria by histamine

1 Achylia by histamine and alcohol, hypochlorhydria by Ewald

1 Achylia by histamine and Ewald; hypochlorhydria by alcohol

19 Total

These results indicate that a small majority of cases showing achylia by the Ewald and alcohol tests will present free hydrochloric acid after histamine stimulation

ADHESIONS (POST OPERATIVE)

There were five in this group.

4 Hyperchlorhydria by all three tests

1 Achylia by alcohol, normal by Ewald and histamine

5 Total

In this group the histamine shows no diagnostic advantage over the Ewald and alcohol tests

COLITIS

Six were included in this group

2 Hyperchlorhydria by all three tests

1 Normal acidity by all three tests

1 Moderate hyperacidity by histamine, normal by Ewald and alcohol

1 Hyperacidity by histamine, achylia by Ewald and alcohol

1 Hypochlorhydria by histamine and Ewald, achylia by alcohol

6 Total

In this group there is certainly no outstanding advantage of the histamine test

GASTRIC NEUROSIS

There were twenty-five in this group

10 Hyperacidity by all three tests

10 Hypochlorhydria and normal by all three tests

2 Hyperacidity by histamine; normal or moderate hypochlorhydria by alcohol and Ewald

2 Achylia by histamine, normal by alcohol and Ewald

1 Achylia by Ewald and alcohol, hypochlorhydria by histamine

25 Total

This survey shows that in the great majority of cases all three fractional studies coincide. The labile character of gastric secretion is emphasized

HEPATO-BILIARY PATHOLOGY

Twelve in this group

5 Hyperacidity by all three tests

2 Achylia by all three tests

1 Hypochlorhydria by all three tests

- 1 Achylia by alcohol, hypochlorhydria by histamine and Ewald
- 1 Normal by alcohol, hyperchlorhydria by histamine and Ewald
- 1 Normal by Ewald, hypochlorhydria by alcohol, moderate hypochlorhydria by histamine
- 1 Normal by histamine and Ewald, achylia by alcohol

—
12 Total

The histamine presents no diagnostic advantage in this group

PTOSIS AND ATONY

Twelve in this group

- 1 Achylia by all three tests
- 6 Hyperchlorhydria by all three tests
- 2 Hyperchlorhydria by histamine, normal by Ewald and alcohol
- 1 Normal by histamine, achylia by alcohol, hypochlorhydria by Ewald
- 1 Normal by alcohol, achylia by Ewald, hyperchlorhydria by histamine
- 1 Achylia by alcohol, hypochlorhydria by histamine and Ewald

—
12 Total

Histamine here gives no advantage from a diagnostic standpoint

PEPTIC ULCER

Thirty in this group

- 20 Hyperchlorhydria by all three tests
- 1 Normal by all three tests
- 1 Hyperchlorhydria by histamine and Ewald, hypochlorhydria by alcohol
- 1 Achylia by histamine and alcohol, hypochlorhydria by Ewald

- 1 Achylia by Ewald, normal by alcohol, hyperchlorhydria by histamine
- 2 Normal by alcohol and Ewald, hyperchlorhydria by histamine
- 1 Normal by Ewald and histamine, hypochlorhydria by alcohol
- 1 Normal by alcohol and histamine, hypochlorhydria by Ewald
- 1 Normal by alcohol, hyperchlorhydria by histamine and Ewald
- 1 Normal by Ewald, hypochlorhydria by alcohol, hyperchlorhydria by histamine

—
30 Total

The superiority of histamine is certainly not proven in this group of cases

SUMMARY

This investigation was instituted for the purpose of determining whether the histamine test is possessed of outstanding superiority over other methods of estimating the acid values in gastric secretion

One hundred cases were selected—a cross-section of dispensary patients—and in these cases every available method was used in order to insure proper diagnosis. In each case three tests—histamine, Ewald, alcohol, using the fractional method—were applied

The results so obtained are tabulated and reviewed, with the following conclusions drawn

1 The Ewald and alcohol meals are effective stimulators of gastric secretion

2 The objection that the swallowing of saliva, the contamination and neutralization of gastric juice by the meal itself, and also the regurgitation of duodenal contents, markedly or ef-

fectually mask the results of these meals *is not sustained*

3 The labile character of gastric secretion is proved

4 Histamine does in a number of cases offer an advantage in establishing the fact that the glands do possess the power of acid secretion when after the Ewald or alcohol test an achylia would seem to be present

5 The alcohol meal is not nearly so potent a stimulant of gastric gland secretion as the Ewald meal

6 There is ample justification for the continuance of the Ewald meal as a dependable test for gastric gland secretion

7 The claim that histamine is vastly superior to the Ewald meal as a stimulant of acid secretion of the gastric glands has been disproved

8 It would really appear that the application of bread and water as a test of gastric gland secretion is more physiologic than the subcutaneous application of the foreign body, histamine, and that it presents a result more in keeping with normal bodily economy

I wish to add a note of appreciative thanks for very valuable assistance so ably rendered by Miss Stearns, Miss Lesser, and Miss Kravetz, of the Gastro-Intestinal Clinic of the Johns Hopkins Hospital in making the tests used in this investigation

The Clinical Significance of Choroidal Tubercles*

By R T PATON, M D, *Baltimore, Md*

BEGINNING about four years after the discovery of the ophthalmoscope we find descriptions of choroidal tubercles in the medical literature. Among the investigators who are associated with these early observations are Jaeger, Von Graefe, Leber, Manz, Bouchert, Gerlach, Fraenkel, and Horner. These descriptions included the two types commonly known as (1) the granuloma or solitary tubercle, (2) choroidal miliary tubercles. The former is usually associated with chronic tuberculosis, and the latter with acute miliary tuberculosis. These observations have been substantiated by later investigators.

Studies of pathological material have shown that the usual number of tubercles in one eye is three or four, but in some cases there may be a much larger number. Morton reported as many as 70, Parsons, 60-70, Cohnheim, 52, and Boch, 49. The size varies from 0.4 mm to 5 mm. Groenouw stated that tubercles smaller than 0.6 mm could not be seen with the ophthalmoscope.

Some observers claim that miliary tubercles are frequent in general miliary tuberculosis. Cohnheim found

them in every instance in the 18 patients he examined, Boch in over 80 per cent, and Carpenter and Stephenson in 50 per cent, while Marple on repeated and careful examination found the appearance of tubercles to be the rule and not the exception. Marple's earlier investigations gave a very small percentage, but this error he discovered was due to failure to make frequent examinations, especially in the late stages of the disease.

Groenouw in a series of cases, including 378 cases of miliary tuberculosis and tuberculous meningitis, found tubercles of the choroid present in 35 per cent of the cases examined either during life or at autopsy. In 222 cases of the series tuberculous meningitis was the clinical and pathological diagnosis, 44 per cent showed tubercles of the choroid. In contrast with these statistics are the figures given by Bredech. Bredech, 1916, after examining the evidence presented by reports, in which careful examination of the fundus had been made, collected a total of 226 cases of tubercular meningitis, in which 14.6 per cent showed tubercles of the choroid. No doubt these percentages would have been somewhat higher had pathological studies been made in every case. He thought that the number would have reached 20 per cent had there also been more frequent examination of the eyes.

*From The Fifteenth Annual Clinical Session at The Wilmer Ophthalmological Institute, of the Johns Hopkins University and Hospital, Baltimore, Md., March 26 1931.

The diagnosis of choroidal miliary tubercle is dependent to a large extent upon the rapid and unexpected appearance of the tubercle. This fact has been stressed by Fraenkel, Groenouw, Lotin, Weis, and many others. Marple reported a case in which an ophthalmoscopic examination, made at 6 P M., did not reveal the presence of a tubercle, but four hours later a tubercle appeared. Moore reported one developing in five hours, while Strider and Weis saw tubercles develop in 12 hours. The discrepancy among various authors as to the existence of tubercles, especially in meningitis, is probably due to two factors: (1) Difficulty in examination—tubercles in these cases are usually found only in the terminal stages. (2) Failure of repeated and careful examination. Tooke reported choroidal miliary tubercles in one case as early as 33 days, but in the majority of cases they did not appear until about three days before death. The clinical examinations in all these cases were verified by post mortem examinations.

Both eyes should be examined. Cohnheim found tubercles in both eyes in 15 out of 33 cases examined. These observations were verified by autopsy and microscopic study.

The presence of miliary tubercles of the choroid is often a valuable aid before the laboratory tests have been completed, in making a diagnosis in cases suspected of being typhoid fever, meningitis or miliary tuberculosis. Series of cases, in which the value of the ophthalmoscopic examinations is proved, have been published by Bollach, Hillernan and Laporte. Van der Hoeve reported a case of mastoiditis with cerebral symptoms, in

which the existence of miliary tuberculosis had not been suspected until the ophthalmoscopic examination revealed the presence of miliary tubercles. The diagnosis was confirmed at autopsy.

The prognosis in miliary tubercles of the choroid is nearly always bad. Usually there is a meningitis. Jessup, in a series of 15 cases, in which there were tubercles of the choroid present, found that 14 had tuberculous meningitis. Only one case was free from meningeal complications. The clinical diagnoses were confirmed by post mortem examinations.

Solitary or conglomerate tubercle of the choroid is a rare and destructive disease, and is probably always secondary to tuberculous disease in other parts of the body. The affection is usually unilateral, though bilateral incidence has been reported and verified by post mortem studies. The condition is usually seen in the early years of life, but its occurrence has been reported as late as 62 years (Nedden).

Differential diagnosis is often difficult, for we have to distinguish the tubercles from the various malignant growths, such as glioma, retinoblastoma, detachments with massive exudates, etc. In some cases the diagnosis can be made only after the eye has been removed. If the diagnosis is made, enucleation is not indicated unless all therapeutic measures, especially tuberculin, which in recent years has appeared to act favorably in many cases, have failed.

The results of the study of a case of miliary tubercles, which was recently observed, may be of interest.

The patient, a 10 year old boy, was ad-

mitted to the Harriet Lane Home 12 days after the onset of the illness. There was no history of tuberculous contact. On admission the patient was acutely ill. The chief symptoms were headache, nausea, vomiting, drowsiness and mild diarrhea. The boy was temporarily isolated and treated as a case of typhoid. The eye examination made on admission gave the following results:

There was slight suffusion of the conjunctiva, dilated pupils, and slight photophobia. The patient's general condition became progressively worse. Laboratory tests at this stage gave practically negative results. These tests were repeated two days later. Lumbar puncture showed 290 cells per cc., fluid was under pressure, and a

pellicle was formed on standing. The ophthalmoscopic examination revealed slight bilateral optic neuritis with subretinal exudate forming adjacent to the papillae. The veins were engorged and there was definite retinal edema extending out toward the periphery. The diagnosis of tuberculous meningitis was established on the following day, 16 days after the onset of the illness, when tubercles were visible in both eyes. Ocular examinations had been made three or four times a day, so that it is not likely that tubercles had formed earlier in the course of the disease. The patient died two days later. The pathological diagnosis finally established was miliary tuberculosis with meningitis. Tubercles were formed in practically all organs of the body.

Laboratory Methods in Clinical Medicine*

Report of Three Cases

- (1) Diaphragmatic Eventration
- (2) Chronic Nephritis without Hypertension, Cardiac Hypertrophy or Retinal Changes
- (3) Unusual Case of Cholelithiasis

By SAMUEL LEVINE, M D , *Brooklyn, N Y*

FROM time to time the statement is made at medical meetings and in the medical press that the introduction of laboratory methods in the practice of medicine has impaired the physician's powers of observation and his clinical sense, and that, as a result of this, his diagnostic abilities have deteriorated and both patient and physician are thereby the losers

It must be admitted that there is some truth in this statement. The keen sense perceptions of the animal, so important in its struggle for existence, are very much diminished in civilized man (Darwin¹). In his struggles he has developed tools of far greater effectiveness than instincts and sense organs. As a result, these are used much less and have therefore lost some of their power. The fact, however, is that man with his duller perceptions has conquered the animal kingdom, and that portion of mankind that wields the technical power of Western civilization dominates all those races that still retain the primal keenness of their senses

Formerly, the physician, in the practice of his art, was forced to rely upon his senses only, which were consequently developed to a fine degree. But this was due to necessity, not to choice. At present, more accurate methods have replaced them to a certain extent. The thermometer registers changes in temperature much better than the thermesthetic sense; the hemoglobinometer and hemacytometer are much more reliable in the study of blood diseases than the naked eye; and general clinical impressions based upon empirically acquired knowledge have given way to tests based upon scientifically controlled facts. It is doubtful whether these have already resulted in dulling physicians' senses. That the progress of medicine along present lines may have such an effect is very likely. The senses of the physician are no exception to the biologic laws of use and disuse (Darwin²). Nor is this fact to be deplored any more than the general lessening of sense acuity in the entire human race, particularly in its civilized portion.

The following cases illustrate the

*Received for publication, June 5, 1931

value of laboratory methods in clinical medicine

DIAPHRAGMATIC EVENTRATION

History Mr N S, aged 31, automobile mechanic, came to my office Nov 15, 1927. His wife and three children were alive and well. He did not use alcohol and smoked twelve to fifteen cigarettes a day. He had had the usual diseases of childhood. At the age of ten, he was very ill and was confined to bed for a year. The late Dr Robert Schultz, who treated him during that illness, informed me that, "When ten years of age, Mr S was ill with abdominal cramps, diarrhea and vomiting. He lost a lot of weight. Diagnosis was tuberculous peritonitis. He was confined to bed for one year and made a good recovery."

Present Illness In the preceding July, during lunch hour, he was standing in front of the garage where he was employed. The car on which he had been working that morning was raised on a jack in the street near the sidewalk. He saw a truck come along and strike the car, throwing it off the jack. No one was injured. "I said nothing, but in the evening, I felt faint and something was pumping in the left side of my chest." Here he pointed to precordium and left axilla. "I had difficulty in breathing and developed a crampy feeling in my left armpit." Then the following symptoms developed: heartburn, relieved by bicarbonate of soda, not relieved by food, sour eructations, and abdominal cramps after meals. There was numbness in left upper and lower extremities, and in front and behind left ear. He had nightmares and dreamt he was falling from some great height. Patient had to give up his position and went to the country for a rest, without any improvement in his condition.

Examination The patient was a medium-sized, hairy male. He had two accessory rudimentary mammae on each side, below and to the inner side of the normally placed mammae, undeveloped and adherent lobules of both ears, and a remarkably large penis. The pulse rate was 72. The blood pressure was 126 systolic and 60 diastolic

in both arms. His weight was 125 pounds (56.8 Kg). Dull tympany was present below left scapula with diminished vocal fremitus and absent breath sounds. After radiographic examination and when *purposefully looked* for, the following were noticed. When stomach was empty, there was dull tympany at the base of the left lung and the heart was only slightly displaced to the right. When the stomach was full, the heart was much more displaced to the right (Assman²), and the base of the left lung was flat. Splenic dullness could not be elicited because of marked tympany in that area. The left lower chest was flattened, more so over precordium. While the chest expanded with inspiration in a normal manner, the intercostal spaces retracted, particularly over precordium.

Radiographic examination showed that the left dome of the diaphragm was high and moved slightly downward with inspiration. The heart was displaced to the right (figure 1). Barium gruel was then administered. Fluoroscopy of stomach revealed that the greater part of it was situated under the lower left ribs. The air bubble was large. The fundus rested against the diaphragm. Body and pylorus were situated in the left side of abdomen. The incisura angularis was absent and the pyloric part ran straight downward. The duodenum was pulled over to the left. The stomach emptied rapidly (Figure 2).

A barium enema was given and it was noticed that the hepatic flexure of the colon formed an obtuse angle and the transverse colon ran upward and to the left (figure 3).

Cholecystograms taken after the administration of tetra-iodophenolphthalein by mouth, revealed the gallbladder faintly outlined and with poor concentration. This was probably due to the abnormal position of the duodenum which interfered with the normal function of the papilla duodeni.

Proctoscopic and sigmoidoscopic examinations were negative. Urinalysis was negative. Two out of three specimens of feces gave a faintly positive reaction to the benzidine test. Blood examination was negative except for an increase in the icteric index which was 10.7, probably caused by the displacement of the duodenum which interfered

with the patency of the common bile duct. The blood Wassermann reaction was negative and the blood count was normal.

COMMENT

This man was seen by several good clinicians, who, in view of the history and symptoms made a diagnosis of neurosis. Some of them also thought that he had a lesion in the left lung.

These patients are usually diagnosed as neurotics and psychopaths. Friedrich Schneider in 1900, the first man with diaphragmatic eventration to be studied with the roentgen rays, told Dr. Hirsch⁴ "Many doctors did not believe that I suffered." Leichten-

stern's⁵ patient with diaphragmatic hernia was considered by him as a "simulant", a neurotic, and he really acted as such. This has also been the experience of Carman and Fineman⁶, Soresi⁷, Funk⁸, and Funk and Manges⁹. Walton¹⁰ writes, "During the past ten years, there have been more authentic cases of eventration reported than in the previous 139 years, when Petit first reported his case." "Clinically", says Hitzenger¹¹, "this diagnosis can only be surmised, without the aid of the roentgen rays, it can hardly ever be made." During eight years in a very active radiographic

FIG. 1. Case 1. Left dome of diaphragm high. Heart displaced to the right. This film was made one hour after dinner.

service he saw twenty cases of eventration. So many cases have been reported in recent years that Hitzenger thinks it is fortunate that not all observed cases are published.

It is of real clinical importance to recognize this condition because a mistaken diagnosis may have serious consequences. Since the physical signs in the lung strongly suggest the presence of fluid, a needle may be introduced which would enter the stomach with, perhaps, fatal results (Pepper¹², Stilvelman¹³, Clopton¹⁴, Allan¹⁵).

The question now arises whether his long illness at the age of ten was

not due to diaphragmatic eventration. It is idle to speculate now, but it is very likely, in view of the protean manifestations of this disease and its periods of complete freedom from symptoms, that a diagnosis of tuberculous peritonitis would have been changed to diaphragmatic eventration, had the roentgen rays been used at that time.

CHRONIC NEPHRITIS WITHOUT HYPERTENSION, CARDIAC HYPERTROPHY OR RETINAL CHANGES

History Miss R Z, aged 23, single, came to my office May 11, 1929. She was employed in a candy factory up to two years

FIG 2 Case 1 Esophagus, stomach and duodenum. Note position of cardia and large air bubble.

ago, since then she has assisted her mother in her household duties. Menstruation began at the age of sixteen and occurred every twenty-eight days, lasting three days. Habits normal. She had had the usual diseases of childhood including diphtheria and scarlet fever, for the latter of which she was kept in a hospital for contagious diseases for three months.

The patient, as well as her mother, denied that she had ever had kidney disease or that she was ever edematous. Her tonsils were removed two years before, and up to that time she had had frequent attacks of sore throat. The appendix was removed five years ago. Eight months before, she experienced dull pain in the epigastrium which was not severe and did not radiate. This pain had no relation to meals and was not relieved by vomiting or by bowel movement.

Occasionally, she awakened at night with pain. During the first month of illness she vomited soon after meals, even the sight of food produced vomiting. Since then, she has vomited only at rare intervals, mostly in the morning before breakfast. The color of the vomitus was that of the food ingested. She had severe heartburn which was relieved by an alkaline water. She belched a great deal and there was a sense of heaviness in epigastrium. Her appetite had been poor throughout her life. During this illness, she had lost thirteen pounds. Her bowels were quite regular up to nine months before, since which time she has taken a daily enema or cathartics. No blood or mucus was noticed in the stools. Nocturia, frequency or dysuria, cough or dyspnea on exertion had not been noted. There was an occasional slight headache, no dizziness or

FIG 3 Case 1 Colon and stomach filled simultaneously

visual disturbances. She slept quite well but for the epigastric pain.

Examination The pulse rate was 108, blood pressure, 110 systolic and 80 diastolic in both arms. The weight was 86½ pounds (39.3 Kg). The patient was a thin, narrow individual, and her face was grayish-pale, the thyroid gland enlarged, no thrill felt or bruit heard over it, there was marked tremor of both hands, no exophthalmos present, Graefe and Moebius signs were absent, no hypersensitive skin zones present. Liver and spleen not palpable. The abdomen presented a scar due to appendectomy. There was marked epigastric tenderness.

A casual specimen of urine gave a slightly alkaline reaction, the specific gravity, 1010, a moderate amount of albumin, no sugar, microscopic examination, negative. Two blood-chemistry examinations were done in an interval of four days and gave the following results: Urea nitrogen, 16.6 to 19.2-3 mgms, creatinine, 4.3 to 4.5, sugar, 108.1 mgms, icteric index, 5, blood Wassermann reaction was negative. A urine concentration test was then carried out. The patient brought two specimens taken at 8 a.m. and 10 a.m., of which the specific gravity was 1009 and 1010 respectively. Two blood counts were taken in a four days' interval and showed 62 per cent to 57 per cent hemoglobin (Sahli), 3,500,000 to 3,100,000 red blood cells, 9,400 to 7,400 white blood cells. The differential count showed 54 per cent polymorphonuclear leukocytes, 27 per cent small and large lymphocytes, 2 per cent transitionals, 12 to 17 per cent eosinophiles. The red blood cells were very pale. There was considerable poikilocytosis and anisocytosis and an occasional microcyte was seen.

In view of the persistence of eosinophilia, the stool was examined for ova. We observed structures which suggested to us the ova of *Uncinaria americana*. In order to check up on the diagnosis of a disease with which we were not familiar, we had arranged to send the stool to a competent parasitologist who had a great deal of experience in tropical diseases. Unfortunately, the patient's relatives refused to cooperate. Perhaps it ought to be mentioned that this patient had never visited a tropical country. The benzidine test was negative. There was free hy-

drochloric acid present in the gastric contents.

The eye grounds were examined by an ophthalmologist who found "both fundi entirely negative."

Radiographic examination revealed no abnormalities in heart and lungs. A barium test meal was then administered. There was no evidence of organic disease in stomach or intestines. There was considerable gastrop-tosis, stomach reaching 12 cm. below the crest of the ileum, duodenal stasis was present to a considerable degree. After five hours both stomach and duodenum were empty.

The patient died eleven months later.

COMMENT

This patient had been treated for six months for gastric ulcer by an eminent gastroenterologist, thoroughly acquainted with his specialty and on the teaching staff of a large university. Nevertheless, a blood urea done by a competent technician would have done more to point towards a proper diagnosis than all the experience and learning of this clinician. The presence of albumin in the urine does not have the same significance as the high urea in the blood. Had this patient presented all the classical symptoms of chronic nephritis, the clinical diagnosis would have been evident and laboratory methods might have been dispensed with or only used to corroborate it. However, this was an atypical case (Bannick¹⁶, Bennett¹⁷, Fishberg¹⁸), and offered little, if any, clinical evidence of the true condition. Here, the clinical laboratory, impersonal and objective, made the diagnosis.

* * *

UNUSUAL CASE OF CHOLELITHIASIS

History Mrs. S. L., aged 55, born in Russia, came to my office, Jan. 10, 1929. She

had been married 36 years and had never been pregnant. The menopause set in ten years before. When in Russia, she had the following diseases: pneumonia at the age of 18, malaria at 25, cholera at 29 and typhoid fever at 36. She had had two minor operations on the uterus per vaginam, one at 27, and the other when 30 years of age. Their exact nature could not be determined. At 40 she was operated upon for an ischio-rectal abscess, at 46 a left intraligamentous cyst was removed. One year before, she had an attack of severe cramps and pressure in epigastrium, which radiated to the back, was worse after meals, but was relieved by bowel movements. The pain was so severe at times that it kept her awake at night. Within the last month she had lost nine pounds, and in the preceding eleven months, twenty-one pounds. She was never jaundiced.

Examination There was definite and constant tenderness and rigidity in the right upper quadrant of the abdomen. Rocking the liver caused much pain. The history and physical findings were so typical of cholelithiasis that this diagnosis was made on clinical grounds by Dr. Joseph Rivkin who first saw this patient. I readily concurred in the diagnosis.

Examinations of urine, feces, gastric contents and blood were negative.

A barium test meal was administered. Radiographic examination of gastro-intestinal tract revealed a normal stomach, duodenal cap was indented at its outer border by an oval mass and a dense tube projected from the lower part of this mass (figure 4). After five hours, the stomach was almost empty, but the oval mass with the tube remained unchanged and continued so on the twenty-four, forty-eight and seventy-two hour plates.

FIG. 4. Case 3. Duodenal cap is indented at its outer border by an oval mass. A dense tubular-appearing shadow projects from the lower part of this mass.

Cholecystograms were taken sixteen hours after administration of tetra-iodophenolphthalein by mouth. The gall bladder was not visualized and only the structures described above were seen. Roentgenograms were then taken twelve days, four weeks and six weeks later. The findings remained unchanged up to the six weeks' plate when a slight change was noticed (figures 5 and 6).

Interpretation of the plates was difficult. It was thought that a duodenal diverticulum was present. However, since the symptoms continued, patient submitted to an operation which was performed by Dr. John Linder at the Brownsville and East New York Hospital. The operative findings were as follows: The dense, tubular structure represented the lower part of the gall bladder which was tightly filled by a lime cast. The

oval mass above it represented the upper part of the gallbladder and was tightly filled by a large cholesterol stone.

COMMENT

In this case the clinical diagnosis was correct while the roentgenograms only served to confuse us. This much must be admitted. The real fault, however, did not lie with the method but with its incorrect application. Had I taken a plain plate of the abdomen *before* administration of barium, a duodenal diverticulum scarcely could have been suspected, and the diagnosis of gallstones would have suggested itself. Renal stones could have been ex-

FIG 5 Case 3. After twelve days, the oval mass and dense tubular shadow remain unchanged.

cluded, if necessary, by pyclograms. Furthermore, had this precaution been taken, the exact size and shape of the stones could have been predicted accurately, whereas, clinically, this was impossible. It is therefore clear, from this case, that in the radiographic examination of the abdomen, no barium is to be administered before a study is made without it.

CONCLUSIONS

Laboratory methods in clinical medicine have recently been subjected to severe criticism on the ground that they tend to impair the physician's

powers of observation and his clinical sense. In defense of these methods I wish to emphasize (1) that they are an extension of the clinician's senses, a gain far outweighing any possible loss of sense acuity, (2) that the careful application of these methods is responsible for most of the progress we have made, and (3) that they are not intended to replace older clinical procedures.

The shortcomings of the laboratory are undeniable. These can be overcome only by giving further attention to their improvement, and not by reverting to the sole use of the unaided

FIG 6 Case 3 After six weeks, the dense tube is surrounded by a lighter oval area

senses and to such vagaries as "personality" and "intuition"

My conclusions are illustrated by the following cases

1 Diaphragmatic eventration This patient had been diagnosed as a neurotic His history and behavior strongly suggested this, but the roentgen rays revealed his true condition

2 Chronic nephritis without hypertension, cardiac hypertrophy, or retinal changes This was an atypical case in which all the cardinal clinical symptoms of chronic nephritis were absent On the contrary, the symptoms were so strongly indicative of gastric ulcer that for six months this

patient was treated for this condition by a competent gastroenterologist Without the chemical study of the blood, the diagnosis was almost impossible

3 Unusual case of cholelithiasis This was correctly diagnosed by the history and physical examination, but was confused by the improper use of the roentgen rays Had a plain plate of the abdomen been taken before administration of the barium, this error might have been avoided This case, then, illustrates the value of the older clinical methods as well as the importance of using the newer methods properly

Auriculoventricular Nodal Rhythm*†

With Report of Cases

By CARL V. VISCHER, M.D., F.A.C.P., and LOWELL L. LANE, A.B., M.D.,
Philadelphia, Pa.

EXPERIMENT has demonstrated that not only the sinus node but the A-V node, the auriculoventricular bundle of His and the bundle branches, with their arborizations have the capacity for impulse production. This fact was established by the Stanis' ligatures. If a ligature is tied around the sinus of a frog's heart, or placed below the level at which the cardiac rhythm is generated, the heart ceases to beat temporarily below the level of this ligature, but after a brief standstill takes up a regular rhythm of its own. This new rhythm is generated in a lower center and is slower in rate than the original sinus rhythm. Likewise if a ligature is placed at the auriculoventricular border a short pause in the contractions is followed by the initiation of a new rhythm which has its origin in the ventricle (idioventricular rhythm), and is still more retarded in rate. These experiments demonstrate that the lower centers have the capacity for impulse production and that the lower the origin of the impulse in the Purkinje system the slower is the rate of impulse generation. In other words

the rôle of pacemaker normally held by the sinus node may, under certain circumstances, be usurped by one of the lower centers.

The center producing the fastest rhythm always controls the heart. As long as the sinus node remains the center of most rapid impulse generation it retains the rôle of pacemaker. The lower centers may gain control over the heart under one of three conditions: in case of depression of sinus rhythmicity, interruption in conduction, or increased excitability of a lower heterotopic center. As long as the sinus node retains its normal rhythm the rapidity of the impulse formation destroys the stimulus to impulse production in the lower heterotopic centers, thus preventing their functioning.

Depression of the sinoauricular node usually results in the automatic transference of the function of impulse production to the auriculoventricular node. This is the phenomenon of nodal rhythm. Experimentally such a condition may be produced by a number of different procedures. Destruction of the S-A node or obliteration of its blood supply will result in the establishment of a nodal rhythm. Cooling of the S-A node will produce the same result. Increased excitability of the

*From the Department of Medicine, Hahnemann Medical College and Hospital, Philadelphia, Pa.

†Received for publication June 1, 1931.

A-V node, caused by a warming of this structure, precipitates a similar transference of the pacemaker. Lewis has demonstrated that nodal rhythm may also follow interference with the nerves of the heart, especially combined stimulus of the right vagus and left sympathetic nerves.

It is now generally accepted that the A-V node is responsible for certain rhythms, characterized by simultaneous contraction of auricle and ventricle. Proof that such a rhythm has its origin in the A-V node was shown by the following experiment. If, during auriculoventricular rhythm, the septum is cooled on the ventricular side of the node, or as Meakins has demonstrated if the bundle is clamped, the ventricle fails in its responses, while the auricle continues to contract. Probably the most convincing evidence that the new rhythm arises in the A-V node is that the rhythm is retarded by cooling and accelerated by heating the region of the node.

Experiments by Lewis have shown that the right vagus has a greater retarding influence upon the sinus rhythm than has the left. The influence of both vagi on rhythm production in the A-V node is powerful. The left sympathetic nerve seems to accelerate rhythm production in the A-V node markedly and to a greater extent than the right nerve, as shown by the fact that isolated stimulation of this nerve may suffice to induce an A-V rhythm.

Clinically the action of the vagus is probably responsible for the depression of the S-A node. The A-V node is then allowed to escape. An escaped beat is a contraction resulting from a

stimulus from a lower center and occurs when there is a long pause in the sinus rhythm as in expiration, blocked auricular extrasystole, sinoauricular block, compensatory pause in ventricular extrasystole or partial heart block. An escaped beat differs from an extrasystole in that the former occurs late in the sinus interval, while the latter is a premature contraction. The incidence of an escaped beat is not infrequently noted, but a true nodal rhythm is relatively rare. Auriculoventricular rhythm may be considered an escape phenomenon and is actually a series of escaped beats.

A temporary nodal rhythm may occur during the vagal slowing of the heart on expiration. Atropine, through its effect on the vagus, will usually abolish an auriculoventricular rhythm, although in some cases this result is not obtained. The same drug may initiate a nodal rhythm. This effect is attributed to a primary stimulating effect on the vagus. An increased excitability of the A-V node may account for the failure of atropine to abolish nodal rhythm in some cases. It has been demonstrated both experimentally and clinically that the vagus is capable of controlling the rhythm produced in the A-V node. Stimulation of the sympathetic by exercise may abolish such a heterotopic rhythm.

Electrocardiographic tracings in instances of nodal rhythm exhibit several characteristic features. The initial and final deflections of each individual complex show the same features as are noted in the nodal type of extrasystole: first, a negative or inverted P wave due to retrograde conduction in the auricle, and second, a shortened P-R

interval Rarely an upright P wave is encountered, which is explained either as a mechanical stimulation of the auricles by ventricular contraction if the P wave follows the QRS complex, or by a variety of intraauricular block with deviated conduction in the auricle The ventricular complex is of the normal supraventricular type The P wave may precede the QRS complex, become buried in it, or follow it, depending on the origin of the stimuli, whether it be in the upper, middle or lower portion of the A-V node (figure 1) The last type in which the stimuli, for contraction, arise in the lower zone of the node is the one most commonly noted in the graphic tracings In such an instance the ventricular contraction precedes the auricular beat, thus giving rise to an R-P interval in place of the normal P-R interval of sinus rhythm A résumé of two cases observed within the past year is here presented

Case I A man, aged 46 years, admitted to the medical ward with the complaints of dyspnea and of cough No information of clinical importance could be obtained from his past history He first noticed shortness of breath two years previously This had increased progressively, and was accompanied by a cough productive of blood-streaked, watery sputum several days previous to admission Examination revealed a cardiac enlargement to the left, a poor cardiac muscle tone, and a mitral systolic murmur The pulse was regular in rhythm, rate 52, and the blood pressure 210/130 There was evidence of congestion at both lung bases A Wassermann test taken the day after admission was negative The patient failed to respond to appropriate medication, dyspnea increased, pulmonary edema supervened, a progressive fall in the systolic blood pressure was noted, and he died three days later of cardiac failure

It is interesting to note that the pulse rate remained between fifty and sixty until

the time of death, despite the failing cardiac function This clinical factor was suggestive of heart block An electrocardiogram taken two days before death revealed an auriculo-ventricular nodal rhythm with the characteristics previously described (figure 2)

Case II A woman, aged 43 years, had been troubled with palpitation and dyspnea, with occasional precordial pain on exertion for a period of several weeks Three years previously she had received treatment over a period of eight months for an active luetic infection, resulting in a negative Wassermann reaction The patient stated that she was quite well until the onset of the above features in February of the current year Clinical examination showed evidence of cardiac enlargement to the left, by physical signs and fluoroscopy, an apical systolic murmur and an accentuated high-pitched aortic second sound The pulse was regular, rate 50, and the blood pressure 130/80 There was no evidence of congestive heart failure A diagnosis of cardiovascular syphilis seemed justified Electrocardiographic tracing made at this time showed the presence of an A-V nodal rhythm (figure 3)

This patient received 1/25 grain of atropine sulphate hypodermatically to note its effect on the cardiac rhythm A tracing taken fifteen minutes after injection showed a persistence of the nodal rhythm, with some increase in rate (figure 4) This result may be explained either as a primary stimulating effect on the vagus, or an enhanced activity of the A-V node Six days later, with the return of sinus rhythm (figure 5), it is interesting to note that the patient experienced marked improvement in her symptoms of dyspnea and precordial distress

The phenomenon of auriculoventricular nodal rhythm is a rather rare clinical finding In a survey of the last 1800 tracings taken in the Electrocardiographic Department of Hahnemann Hospital only four cases were recorded The condition is usually recurrent in character and of short duration It is often noted in alternation with normal rhythm In unusual cases the

FIG 1 Examples of three types of nodal rhythm. The upper tracing shows inverted P wave preceding the ventricular complex, resulting from impulses originating in the upper portion of the A-V node. In the type exemplified in the middle tracing the impulses arise in the middle portion of the node, causing a simultaneous contraction of auricle and ventricle. The P wave is buried in the QRS complex. Lower tracing shows most common type of A-V rhythm in which the lower portion of the node is site of impulse generation. Inverted P wave follows QRS complex.

FIG 2 Electrocardiographic tracings of case I, showing A-V rhythm of most common type, with negative P wave, preceded by the ventricular complex.

FIG 3 Graphic record of case II An A-V nodal rhythm resulting from impulses originating in lower portion of node

FIG 4 Case II following administration of $\frac{1}{25}$ of a gram of atropine sulphate Note persistence of nodal rhythm with some acceleration in rate of impulse production

A-V node may control the cardiac rhythm for weeks, or even months, at a time. Definite clinical evidence of its presence is usually lacking, except that in cases where the auricle and ventricle contract simultaneously, regurgitation from the right auricle may produce a large wave in the jugular vein. In such instances venous tracings will show a more or less simultaneous occurrence of the A and C waves, producing a large single wave. The heart rate is usually slow, between forty and fifty per minute in most cases, which represents the rate of impulse production in the auriculoventricular node.

Such a heterotopic rhythm may or may not be associated with cardiac disease. The two cases here reported did occur with definite evidence of cardiac

dysfunction. Nodal rhythm, *per se*, is an interesting finding, but is apparently of little or no clinical significance. The importance of the condition is evidenced in the necessity of differentiating it from the vastly more serious entity of heart block suggested by the presence of bradycardia, which is common to both disturbances. A bradycardia of sinus origin must also be considered. Diagnosis must usually be made by the electrocardiogram. Prognosis and treatment in cases of auriculoventricular nodal rhythm are entirely dependent upon the associated cardiac pathology.

The authors desire to express their appreciation to Miss Florence Holstein, technician, for her cooperation in preparing the electrocardiograms used in this paper.

Creative Evolution and Prosperity

THE theory of "creative evolution" recognizes the fact that the whole may be more than the sum of its parts. A dog is more than an aggregate of carbon, hydrogen, nitrogen, and phosphorus, supplied with certain energy, and its nature never could be discovered by a study of the elements of which it is made. A symphony orchestra is more than an aggregate of individual musicians. Only when each player finds his personal expression in a unity with the entire orchestra and in contributing to the most perfect total effect does a great symphony appear.

American prosperity, through exceptional circumstances, reached a high crest. That climax of prosperity may prove to have been but the rare crest of a wave if those in business see themselves as independent units, each striving primarily for his own satisfaction. For prosperity of a high type to be permanent it will be necessary for individual and corporate interests to be subordinate to the aim of producing a high and generally distributed well-being. Just as a football team cannot greatly succeed if it is made up of star players each bent on distinguishing himself regardless of the game as a whole, so it is with business.

Those familiar with the motives of some "re-financings" and mergings of the recent past, with the selling of great quantities of stock to the public at high prices, as well as other business practices of the period of prosperity, are aware that the subordination of special interests to the general good is not yet a dominant trait of American business.

Permanent prosperity on a high level will evade us until that spirit is dominant. Except as economists take such factors into account, the disappearance of prosperity will continue a mystery. If creative evolution can take place in our economic life, general prosperity can increase to levels heretofore unknown. It will be better if this comes from the spirit of the times, rather than from enforced government action — (A E M, in *Antioch Notes*, Vol 9, No 7, January 15, 1932)

Somatic Disorders of Functional Origin*†

By S KATZENELBOGEN, M D , F A C P , *Baltimore, Md*

SOMATIC disorders of functional origin present quite a common problem in general medicine as well as in any of its special branches. In dealing with this subject one question immediately arises: Is it possible, or is one altogether justified in drawing a hard-and-fast line between "functional," so-called, and "organic"? Those "organicists" who believe in such a clean-cut demarcation, who are trained to think in terms of lesions exclusively, and to whom therefore complaints and even objective disorders have a meaning only when they can be reasonably explained by a detectable organic alteration, would do well to remember the following facts. In the domain of Neurology, the last three decades have witnessed an extension of the group of organic diseases of the cerebrospinal nervous system at the expense of the group of functional diseases. I allude to such diseases as chorea, athetosis, Parkinson's disease, and Thompson's disease, which have been successively transferred from the functional into the organic group. This fact may be grati-

fying to the organicist, but it should also serve as a warning against a loose attitude towards functional disorders, which, for many physicians, under the label of "neuropathy," are quite equivalent to "imaginary malady." I should also like to call your attention to some facts in other domains. Clinical and anatomic-pathological observations have brought to light the concept that the morbid manifestations of such an organic disease *par excellence* as angina pectoris appear to be controlled by a functional factor. Such a belief has its basis in the fact that one finds on post-mortem examination sclerosis of the coronary artery in persons who never had *anginal attacks*. Moreover, in certain patients who did suffer from typical attacks of angina pectoris, and displayed evidences of a marked excitability of the vegetative system, the anatomical examination did not reveal lesions in the myocardial vessels, nor could any lesion of the vegetative system be discovered. It has also been found that the occurrence and frequency of attacks in such organic diseases as symptomatic asthma and biliary lithiasis are more or less conditioned by the functional state of the autonomic nervous system. These observations sufficiently demonstrate the fragility of the lines drawn between organic and functional. Besides, the

*Presented at the Fifteenth Annual Clinical Session of The American College of Physicians, March 25th, 1931, Baltimore, Md.

†From The Henry Phipps Psychiatric Clinic (Department of Internal Medicine) Johns Hopkins Hospital, Baltimore, Md.

usual opposition of "functional" versus "organic" does not seem to rest upon a sound basis, for the so-called functional disorders are associated with definite changes in secretion and motility of organs, they are accompanied by alteration of the physicochemical status of the blood and other bodily fluids. These modifications present organic disorders going hand in hand with the altered function, and, needless to say, are capable of causing as much distress as structural disorders. It would therefore seem more appropriate to use the term physiogenic as applied to both "organic" and "functional" disturbances, bearing in mind that in organic disorders the altered function is accompanied by histological changes and in purely physiogenic disorders, only physicochemical changes may be found. As to the "psychogenic bodily disorders" they are obviously also attended by altered physiological functions. The term psychogenic only implies the notion that certain psychological factors take part in the causation of the physical disorders. Functional hyperchlorhydria, for instance, may be induced by certain physical stimulants, highly seasoned food, alcohol, or by affective disorders, in which case it will be of psychogenic origin.

In this necessarily sketchy presentation, I should like to bring to your notice some of the commonest functional disorders. Pain is one of these troubles and it calls for special attention not only on account of its distressing, incapacitating effect, but also because this is a warning that something is wrong. Excluding from the discussion pain associated with detectable physical disease, one may ask whether purely psychic factors are able to induce pain in

apparently normal individuals? In answering this question I refer to the following two cases, which, in my judgment, illustrate psychogenic pain.

1. A man, 43 years old, graduate chemist, had suffered from a severe attack of sciatica for over a year. The recovery was complete and no relapse had taken place during the six years he was known to me. He presented, however, the following curious phenomenon. On many occasions when reminded of his previous illness, or when he was thinking about the possibility of a recurrent attack, he experienced severe, but fortunately very transitory pain in his leg, without developing, otherwise, neurasthenic or hysterical features.

In the second case, suggestion of a very protracted character was evidently the cause of the evil.

A young man, a medical student, had been suffering from dull pains in the back of the head. The history revealed that the trouble started after he had been painfully impressed by the death of a classmate from cerebral tumor. Notwithstanding the fact that his fear of also having a tumor was dissipated by the entirely negative physical examination, his head sensations, more or less pronounced, had persisted during the four years I knew him.

Psychogenic pain may also be exemplified by the following two cases observed in this clinic.

A woman, among other troubles, complained of soreness of the tongue. This complaint became particularly prominent and persistent after a suspicious diagnosis of cancer, based on some enlargement of the papilla on the base of the tongue, was made. The patient continued complaining of pain long after the local symptoms had subsided.

Another patient came to this clinic because of attacks of soreness of the tongue which had taken place on several occasions during her lessons in school and for which talking was blamed. I must add that there was a certain physical background in the beginning, namely, throat and sinus troubles which may raise the question of referred

pain But during her stay here, in spite of the fact that she still had remnants of her previous condition in the throat and antrum and was very talkative, she did not have any pain It therefore seems plausible to assume that we are confronted here with pain of recollection analogous to the case of sciatica which I have just recorded The fear of losing her position should attacks of pain which she originally experienced while teaching recur, made her on certain occasions think vividly of this experience during her lessons and feel accordingly

As to the mechanism of psychogenic pain, the following conjectures may be considered 1 Psychic stimulation with response of certain areas of the brain, such as the thalamic region, center of pain sensations, from which pain is projected to the periphery, as it is assumed to be in organic central pain 2 Pain is known to be frequently associated with vasomotor disorders regarded by some writers, not without plausible reason, as the immediate cause of pain, be it of central or peripheral origin The last mentioned hypothesis seems the more plausible because pain is a common complaint of psychoneurotic individuals who, besides, usually display evident vasomotor disturbances.

Another complaint not substantiated by somatic findings is fatigue It may have but little bearing on the muscular strength or muscular tone It will be found that this type of fatigue is rather closely related to lack of interest in the particular effort which causes it, and may therefore be termed selective fatigue Being functional this kind of fatigue is, however, not infrequently associated with loss of weight, as a result of loss of appetite, and inadequate food intake

Functional cardiac troubles constitute perhaps the most conspicuous

chapter in functional pathology Their symptomatology shares, with that of functional disorders of other vital systems, the common character of being mainly subjective Sensation of pressure, pain in the cardiac region, sometimes with radiation to the left arm, palpitations, inability to take a deep breath are common complaints The latter, usually of a rich variety are, however, not referred to the heart only The objective examination will reveal symptoms with which we are all familiar, such as tachycardia of the transitory type, hyperkinesis, extrasystoles, systolic murmurs usually localized in the mesosternum, and vasomotor lability Here I should like to call attention to a special type of cardiac neurosis That is the syndrome known in the literature of war neurosis as "irritable heart of the soldier", or more commonly in the general medical literature as "effort syndrome", or "neuro-circulatory asthenia" As the last named term suggests, the troubles are referred to both the circulatory and nervous systems

In addition to complaints and objective symptoms common in functional heart disorders, there are other features which dominate the clinical picture Fatigue, usually more pronounced in the earlier part of the day, dizziness, giddiness particularly liable to occur when the sitting position is changed to a standing one, general shakiness, fainting, with or without complete loss of consciousness, excessive susceptibility to cold, sleeplessness, inability to fix the attention, and lack of interest This syndrome may be found in juvenile cases, and in adults, and is not infrequently responsible for the accusation of "laziness" among school boys

and girls. In many cases a constitutional origin is suggestive. In others, this syndrome appears to be a sequel of a toxic-infectious condition. In the last named cases one will be confronted not infrequently with the dilemma as to whether the protracted effect of the toxic-infectious condition is solely to be blamed, or whether the oversolicitous family or doctor are not partly responsible for keeping the patient away from his duties longer than is absolutely necessary, with the consequent worries about waste of time and loss of the patient's selfconfidence.

Finally, I want to call attention to some of the functional gastrointestinal disorders. Numerous experimental investigations and clinical observations of patients with gastric fistula, observations having the value of experiments, are available, which point to certain etiologic factors of the so-called nervous indigestion. These studies demonstrate that affective imbalance, and mainly acute emotion (anger, anxiety, fear, etc.) strongly influence the gastric secretion. The latter usually increases under pleasant emotions (sight or smell of food, pleasant environment while eating) and decreases under unpleasant ones. This relationship between secretions of the digestive system, and emotions is an old notion familiar even to laymen, as indicated by the ancient test used in India to pick out a thief from a group of suspicious persons, a test in which each person is given a bowl of rice and the criminal is detected by his dry mouth, and inability to insalivate the rice.

The motor function of the alimentary canal may be equally controlled by psychic factors. Here again I refer to the common observation of physiolo-

gists, demonstrating that uneasiness, discomfort, and anger, experienced by animals, immediately induce cessation of the gastrointestinal movements. If under these conditions the splanchnic nerves are cut, the inhibition will be reduced to a great extent. On the other hand, clinical and radiological investigations on men, also demonstrate the inhibitory or stimulating effect of emotion on the gastrointestinal motility. The barium meal may remain in the stomach for many hours without moving, in individuals under nervous strain in whom no organic alteration is recognizable. Psychic stimulation may also have the opposite effect, namely, to increase the motility. In this respect the following case may be illustrative.

A man who, in his capacity of a high official in an international institution, had to attend banquets and various social gatherings, suffered from the following trouble. On many of these occasions, as soon as he started eating he had to leave the table, summoned by the call of nature. No organic cause for this trouble could be detected. On the contrary, the history of the disease was very illuminating. This man had been brought from obscurity into prominence during a revolution in his country. From a modest social standing, an humble member of the socialistic party, he suddenly found himself a representative of his country in the institution of highly trained diplomats. This turning point which threw him into a *milieu* and conditions not usual to him, was the beginning of his troubles, obviously on an emotional basis.

Finally, radiological examinations showing the reverse current in the digestive tract in certain patients, while under emotional strain, substantiate the clinical observations of vomiting in neurotic individuals, in whom no causes other than effective disturbances can be revealed.

The problem of etiology, pathogenesis of functional disorders in general, and of the gastrointestinal disorders in particular has given rise to theories implicating the autonomic nervous system. These theories advocating the conception of sympathicotonia and vagotonia, that is, of an imbalance between the two antagonistic parts of the visceral nervous system, had a wide vogue after they were propounded by Eppinger and Hess in 1910. Now, we should all be familiar with the fact that the subdivision of neurotic individuals into two clean-cut reaction types is not warranted by clinical observation. It is true that in certain subjects there are evidences suggestive of a certain predominance of one set of the vegetative nerves—the sympathetic or the parasympathetic. But what we commonly meet with in neurotic individuals is a disturbed function involving both portions of the visceral nervous system. One usually observes a dystony which may manifest itself not only by a relative increase of the controlling power of one portion, but also by an increase or a lowering of the tone of the whole visceral nervous apparatus.

From the etiologic standpoint the malfunction of the autonomic nervous system raises the question of the rôle of constitution, the rôle of toxic-infectious conditions and other physical factors. Another element weighing heavily in disorders of the viscera under the control of the vegetative system, an element which is commonly not given adequate consideration by the physician at large, by the internist, and general practitioner, is the emotional one. Of course, the relationship of cause and effect is open to debate. One may ask whether the excessive responsiveness

of the visceral organs to certain life situations is conditioned by inherent or acquired malfunction of the autonomic nervous system or of the viscera themselves under its control, or are these excessive reactions only a proportionate response to strong emotion proper to the psychobiological endowment of the individual involved? Leaving this question out of the discussion it suffices for our purpose to note the fact that affective imbalance, arising from life conflicts and not infrequently from pleasant life experiences also, is attended by more or less pronounced reactions of the vegetative organs. Moreover, it is well to bear in mind the notion ably advocated by Cannon, that affective disorders, when they repeat themselves, are able to sensitize the vegetative system which will then react excessively, even to a mild emotional upset.

In concluding I would like to emphasize the three following points:

- 1 The so-called functional disorders are not "imaginary maladies," and they may cause as much discomfort and distress as organic structural diseases.

- 2 Functional disturbances may be induced by various factors, physical as well as psychological.

- 3 A thorough physical examination should therefore be supplemented by a no less thorough inquiry into the conditions within and without under which the troubles originated and developed. Such an investigation is obviously imperative whenever no somatic basis for bodily disorders can be found. Moreover, one should be attentive to the fact that manifestations of organic-structural diseases may also be greatly influenced by psychological factors.

Advanced Pulmonary Tuberculosis*

By LEWIS J. MOORMAN, M D , F A C P ,† *Oklahoma City, Oklahoma*

FOR many decades the dominant theme of practically all discussions dealing with clinical tuberculosis has been early diagnosis and early treatment. While the significance of this theme is perfectly obvious and the difficulty of early diagnosis universally admitted, there still seems to be a general lack of interest in tuberculosis. This may be accounted for in part by the fact that, until recently, we have been unable to offer any constructive variation in a program which often proved inadequate. It is not surprising that many members of the profession not particularly intrigued by the interesting game of physical diagnosis, and not committed to the rather difficult task of phthisiotherapy, should manifest a certain amount of indifference.

Without intensive study there can be little first hand knowledge of the fascinating course of this versatile disease with its ever changing interplay of virulence and resistance, there can be no adequate appreciation of the fact that the relative dominance of these two factors, determines the clinical

course and the pathological variants which range from those manifested through the racing catastrophe of florid phthisis to the relative security of insidious fibrosis. Since tuberculosis continues to be one of the prime factors in morbidity and is responsible for one-seventh of the world's mortality, it deserves the serious interest of the medical profession.

While it is necessary to maintain our emphasis upon early diagnosis and early treatment, it is most gratifying to be able to recount the fact that recent advances in the treatment of pulmonary tuberculosis offer a new hope to those suffering from the more advanced conditions which might otherwise be considered hopeless. Considering the three cases which Dr. Pincoffs has so kindly provided for this clinic, I am indeed pleased to say that our present therapeutic measures are sufficiently flexible to meet many of the wide variations in pulmonary pathology. Many of these variations are exhibited in the cases now to be presented and in addition to the established routine, rest, dietetic and hygienic management, they call for a discussion of the following therapeutic method: artificial pneumothorax, the curettage of pleural adhesions, the various operations on the phrenic nerve and the use of the

CASE I

The first case, C B, is a young colored woman thirty-three years of age, married, no children, but in contact with two children in the home where she is employed to do general housework. Family history negative, except contact with a luetic husband. No history of known contact with tuberculosis. Past history otherwise negative except the loss of about sixty pounds during the past year.

Present Illness In the early part of December, 1930, while at her usual work, she developed a headache, soreness in the chest and weakness. These symptoms were promptly followed by a chill and high fever. A cough and hoarseness developed. After two days she returned to work. Her cough continued and a few weeks later it became productive with a gradual increase in sputum. Three weeks ago, March 3, she had to quit work on account of increasing weakness. She was examined in the outpatient department one week ago and was admitted to the Hospital with a diagnosis of bronchopneumonia, possibly tuberculous in character. Since admission she has shown a temperature range of 99 to 102, pulse 80 to 105, respiration 20 to 30. She has continued to cough and the record indicates that she has raised four ounces of sputum daily.

Physical examination shows limited respiratory excursion on the right, palpation is negative, percussion elicits dullness from the third rib anteriorly to the base. This dullness extends well into the axilla but there is very little impairment posteriorly. The left shows no demonstrable impairment of resonance. Auscultation reveals numerous fine and medium râles over the lower half of the right chest with large bubbling and occasional musical râles on a level with the fourth right interspace anteriorly. These râles are suggestive of the presence of cavity, though there are no other signs to aid in the diagnosis of cavity. With the exception of a few crackling râles along the left border of the heart, auscultation on the left is negative.

An examination of the sputum showed many tubercle bacilli, the blood and urine were reported negative. Blood Wassermann

test was found to be four plus. A flat film of the chest made upon admission shows marked opacity in the lower half of the right lung, suggesting widespread infiltration of varying density. Extending from the lower angle of the right hilum there is an oval density with a rarified center, suggesting a cavity. Stereoscopic films made yesterday present unmistakable evidence of a cavity about five by eight centimeters in diameter. In the parenchyma of the right lung opposite the fourth rib, there is a small calcified node. This, associated with calcification about the hilum, suggests a childhood infection. The left hilum is heavier than normal and there is a generalized fibrosis with a little patchy infiltration in the lower half of the lung (Figure 1).

The diagnosis in this case is pulmonary tuberculosis with rapid caseation and liquefaction with cavity formation. There is evidently an acute bronchogenic spread into the lower right, giving rise to a tuberculous bronchopneumonia. The defensive reaction seems to be wholly inadequate, there is practically no evidence of fibrosis and the course of the disease would suggest that not only has there been a failure on the part of the defensive forces to react with the formation of fibrous tissue, but even the reticulum fibers have gone down under the virulent onslaught allowing the disease to progress rapidly.

However, the patient has shown a progressive gain in general physical well being since admission to the hospital which is encouraging. In spite of the apparently acute course of this case the prognosis is not utterly hopeless. The right diaphragm exhibits a fairly free excursion and it is possible that the pleural space is free. If collapse can be obtained by means of artificial pneumothorax the cavity may

be closed and the progress of the disease arrested

I should advise this course regardless of the slight present trouble on the left side. If the overwhelming load of toxemia can be even partially lifted by pneumothorax on the right we may expect recession rather than progression of the disease in the contralateral lung. If adhesions should be encountered and if they should happen to be of such a character as to justify the Jacobaeus operation (thoracoscopic visualization and cauterization) the handicap of limited collapse might be overcome. If this should prove impractical, phrenicectomy might be indicated. If one or all of these methods should result in marked improvement and yet prove insufficient to close the cavity, cautious employment of thoracoplasty might be considered. If the contra-

lateral lung should happen to take on a progressive phase under such procedures, partial collapse of the left lung by means of artificial pneumothorax might be undertaken, even though it should necessitate simultaneous bilateral pneumothorax. Such a case is not to be considered favorable for any type of treatment, yet the hopelessness of the case if untreated seems to warrant a trial, especially as the results in such cases are occasionally surprisingly good. The presence of an active luetic infection may exert an unfavorable influence through lowered resistance. Antiluetic treatment should be guarded because of the acute character of the tuberculosis.

CASE II

The next case, A W, is a man forty-two years of age. Family and personal history uneventful except contact with father who coughed and expectorated over a period of

FIG. 1. Case I. Advanced pulmonary tuberculosis predominating at the right base large cavity at the right border of the heart extending between third and fifth ribs.

many years While there may be some question as to the diagnosis in the father's case, this cough was attributed to tuberculosis The hospital record indicates that the onset of this patient's present illness was three months ago, when he became too weak to continue his daily routine He developed a cough with moderate expectoration, dyspnea and fever A close investigation with reference to his past reveals the fact that he gives a history of what might be termed a frank pleurisy two years ago and that he has coughed and expectorated for years As may be seen later, this additional history is in keeping with the physical and pathological findings

The patient was admitted to the City Hospital two weeks ago Since this time his temperature has ranged from 98 to 100, his pulse from 72 to 90, respiration from 20 to 30, sputum, four ounces He has manifested symptomatic improvement with some reduction in sputum The laboratory reports show that the blood and urine were negative Sputum showed many tubercle bacilli Physical examination at the present time reveals a well developed man showing no particular evidence of loss of weight Inspection with

reference to the thorax elicits nothing of importance Palpation is likewise negative except for moderate increase in palpable fremitus at the left apex Percussion reveals dullness on the right from the fifth rib up, on the left from the first rib up with slight impairment extending as low as the fourth rib Posteriorly, resonance is impaired on the right from the apex to the lower angle of the scapula, and on the left as low as the fifth vertebra

The right diaphragm is practically immobile Auscultation shows that the breath sounds are slightly diminished over the whole right, but exaggerated at the left apex Fine and medium crackling râles are to be heard over the whole of the right and the upper half of the left At the left apex coarse bubbling and musical râles are heard These signs with exaggerated breath sounds are sufficient to warrant a diagnosis of cavity at the left apex There are no demonstrable signs of cavity on the right side A flat film of the chest presents unmistakable evidence of old fibrocaceous disease at both apices with definite cavity formation at the left (Figure 2) Above the level

FIG 2 Case II Advanced bilateral pulmonary tuberculosis with cavity formation

of the first rib on the left, the film suggests an old pleuritis with marked thickening, giving rise to the so-called pleural cap. On the right side there is a generalized patchy infiltration extending as low as the fifth rib anteriorly. There is also a similar area on the left extending from the hilum and fusing with the old pathology at the left apex.

This widespread dissemination of what appears to be recent disease is in all probability a bronchogenic spread of an old infection and we may be justified in assuming that it is contemporary with the recent exacerbation of symptoms. On the right side opposite the first rib there is an ill-defined thin-walled cavity about $2\frac{1}{2}$ centimeters in diameter. This evidently is likewise of recent origin. The right costophrenic angle is poorly defined and there is obvious peaking of the right diaphragmatic dome suggesting adhesions, which may be dated back to the pleurisy two years ago and which may be utilized to explain marked limitation of diaphragmatic excursion on the right as shown by percussion. You readily appreciate the fact that we have little to offer in this case, yet the low grade toxemia in the presence of such widespread disease suggests a fighting chance. Leaving out of consideration the economic phase of such a case and assuming the possibility of long continued institutional treatment, the following procedure is suggested. Since the acute manifestations are more extensive on the right with a small cavity, the walls of which are not sufficiently fibrosed to materially resist collapse, I would suggest artificial pneumothorax even though adhesions are certainly present. Partial collapse often accomplishes great good and places the pa-

tient in a condition to withstand more radical procedures. In case pneumothorax is impossible on account of obliterating pleurisy or in case basal adhesions are extensive and cannot be cauterized, the pneumothorax may be supplemented by phrenicectomy. If the results of treatment on the right are promising, circumscribed thoracoplasty might be employed to close the old cavities at the left apex.

CASE III

Wm. Y., age sixty, is married and a cigar maker. Past history is negative until five years ago from which time he dates his present illness. Family history is negative. Five years ago he first noticed symptoms of nasal obstruction which was associated with cough. A few months later he had an operation for the relief of this nasal obstruction and something was removed from his nose. His cough continued with increasing expectoration. Three years ago he suddenly developed an attack of asthma which required a hypodermic before he got relief. Since that time he has had wheezing with irregular periods when he would have frank asthmatic attacks. He was admitted to the City Hospital two months ago. His temperature occasionally reached 100, but it has been normal the past six weeks. Pulse, 100 to 120, respiration, 20 to 25, blood pressure, 112/80. Sputum was sixteen ounces daily at first, now about eight ounces. Cough is worse during the night and is paroxysmal in character.

Examination reveals the classical signs of chronic bronchitis with emphysema. Wheezing and crackling râles throughout both lungs. The examination is otherwise negative except at the left apex where are to be found all the signs of fibrocaceous tuberculosis with cavity formation. The trachea is displaced to the right. The reported laboratory findings, including a blood Wassermann test, are negative. Five sputum examinations failed to show tubercle bacilli. With such large quantities of sputum one would naturally expect to find tubercle bacilli if tuberculosis constitutes the chief source of the sputum. In this case there is a his-

tory of asthmatic attacks with long continued bronchitis. It is reasonable to presume that even though the diagnosis of chronic pulmonary tuberculosis is justified there must be some associated condition to account for much of the sputum. Naturally one would suspect a bronchiectasis.

A flat film of the chest as you may see, reveals typical evidence of chronic fibroid tuberculosis at the apex of the left (Figure 3). Strange to say the mediastinum is displaced toward the right, which accounts for the visible and palpable displacement of the trachea toward the right. The lung fields show a generalized fibrosis with rather marked fibrosis extending from the right hilum to the right apex. This latter probably represents an old healed lesion with scar tissue and adhesions which displaced the trachea and heart toward the right, and fixed them in this abnormal position before the fibrotic pull was exerted on the left. There is evidence of diaphragmatic adhesions on both sides and perhaps a slight suggestion of bronchiectasis at the right base.

My impression in this case is as follows: an old healed tuberculous lesion, upper right; chronic caseofibrous

tuberculosis with cavity formation at the apex of the left, chronic bronchitis with bronchiectasis and emphysema. The nose and throat examination revealed a pansinusitis. In this case the sputum should be examined repeatedly, concentration methods being employed. If persistently negative, cultures should be made or animal inoculation employed. The introduction of lipiodol might determine whether or not he has dilated bronchial tubes and whether the dilatations are unilateral or bilateral. If the bronchiectasis is right unilateral as suspected, or if it predominates on the right side, the right phrenic nerve might be taken. Whether or not anything should be done with reference to the upper left will depend upon the progress of the case. The patient's age and cardiac condition would render any major surgical procedure hazardous. Obviously the sinusitis should have appropriate treatment.

FIG 3 Case III Chronic fibroid tuberculosis of the left apex with a possibility of bronchiectasis at the right base

The Diagnosis of Hyperthyroidism*†

By MAYNARD E HOLMES, M.D, F A C P, *Syracuse, N Y*

THE term hyperthyroidism has been adopted in recent years to designate a symptom complex caused by hyperactivity of the thyroid gland. In the past, patients who are now classified as having hyperthyroidism together with a large group with a similar symptomatology but not of thyroid origin, were diagnosed as having Graves' disease. Kessel¹ has called attention to the latter group and applied to it the term autonomic imbalance, to designate it as a disturbance of the autonomic nervous system.

Moschcowitz² is of the opinion that Graves' disease evolves from a basic neuropathic personality to its full-blown clinical form when hyperthyroidism has secondarily developed. Others have described the Graves' constitution, Basedowoid, pre-Basedow and *formes frustes* as precursors of true Graves' disease. Admittedly only a very small percentage of the large neurogenic group ever develop hyperthyroidism, and prior to the development of an elevated metabolism proof is lacking that the symptom complex is in any way related to the thyroid gland, hence for this group some such terms as autonomic imbalance or

neuro-circulatory asthenia more clearly implicates its neuropathic origin. The real problem in the management of these two groups of patients is not so much that an occasional neurotic individual may develop hyperthyroidism, but from a practical standpoint it is far more important to separate the true thyroid patient from the neuropathic one because they demand radically different treatment. It is perhaps unfortunate that the term Graves' disease has not been restricted to those cases having hyperthyroidism, because the two terms are commonly looked upon as synonymous. The confusion brought about by linking the neurogenic group with the thyroid gland not only leads to unnecessary thyroid surgery, but has in the past, been the cause of considerable dissatisfaction with the treatment of hyperthyroidism, and in like manner no doubt explains the disagreement which surrounds the pathology of thyroid disease.

Until the basal metabolism test was introduced as a clinical procedure in 1920, there was no dependable laboratory method to guide one in the diagnosis of thyroid disease. At present, with the help of this valuable clinical test, it would seem that there should be no valid reason for mistaking a neurosis for hyperthyroidism, and yet the error is still commonly made. Ham-

ilton and Lahey³ report that one-third of the patients referred to their thyroid clinic, after careful study fail to show any disorder attributable to the thyroid gland

Failure to differentiate between the true thyroid syndrome and that of neurogenic origin is in great part due to the fact that many practitioners and particularly surgeons seems to underestimate the part played by functional disorders of the nervous system as a cause of many varied symptom complexes. The surgeon, no doubt because of his daily precise technical problems, develops a frame of mind which does not sufficiently evaluate the part functional disorders may play as a great mimic of organic disease. Medical students formerly were so cautioned against making other than an organic diagnosis that later in practice, they lack the courage to do so. The present day student on the other hand, has fortunately a much more rational understanding of the importance of functional disorders of the nervous system as a great cause of ill health.

The following case reports are given to illustrate the manner in which a simple neurosis is frequently confused with hyperthyroidism.

Case I A woman, aged 42, who had always been nervous and in poor health, complained of vague stomach discomfort and fatigue for five years. Anorexia, constipation, pain in the bowels, headache, lame back, sensitiveness to cold, insomnia and palpitation had been present for two years. She had had two Caesarean operations and her appendix had been removed for chronic appendicitis. She had been told by a surgeon that her symptoms were due to thyroid disease, and thyroidectomy urged. To confirm this opinion she consulted an internist

who found a normal pulse, no enlargement of the thyroid and no evidence of thyroid toxicity. The basal metabolic rate was found to be +8. She had always worked hard, and there had always been considerable domestic and financial worries which no doubt were factors producing her symptoms.

Case II A woman, aged 29, was admitted to the hospital with a diagnosis of hyperthyroidism with surgery recommended. Some enlargement of the thyroid had been present since 14 years of age. Nervousness, fatigue, attacks of nausea and vomiting, headache, backache, anorexia, sensitiveness to cold, palpitation, tremor and emotionalism had been present for eight years, or since marriage. There was a marked nervous tendency in her family, one brother having mental disease. The basal metabolic rate was found to be +1. Since marriage there had been considerable family and financial worries. A neurogenic cause for her symptoms seemed quite evident. Several months later after appropriate treatment for her neurosis, she was found to be almost completely relieved of her symptoms.

Case III A woman, aged 34, who was always of a nervous temperament, developed, after considerable marital trouble, increase in nervousness, palpitation, hysterical seizures and fits of depression. There was no loss of weight, thyroid enlargement or sensitiveness to heat. The metabolic rate was -7. A surgeon was inclined to a diagnosis of hyperthyroidism but finally bowed to the opinion of an internist and neurologist that the patient was suffering from a psychoneurosis. The patient seemed obsessed with the idea that her thyroid must be removed and consulted a surgeon in another city. On the basis of a positive Goetsch test, he performed a thyroidectomy. As might be expected from the normal basal metabolism there was no relief of symptoms and within a year the patient was in an institution for treatment of her mental state.

The value of the basal metabolic test in differentiating the thyroid from the nonthyroid patient is often vitiated because of errors of technic or interpretation. When the test was introduced,

Benedict⁴, DuBois⁵ and others cautioned that the procedure could be of little or no value unless performed by one familiar with all the details involved, and using only the most accurate methods. Certain manufacturers have simplified the apparatus and the compilation of the results to such a degree that it is very easy for considerable error to occur. While there can be little doubt that a well trained technician can accurately perform this valuable clinical test, it is quite another thing to have it performed as it commonly is by one who has had no training except perhaps from a circular or a salesman. The performance of this test which carries so much weight in diagnosis should be as carefully guarded as, for example, the Wassermann test.

Perhaps the greatest error in the interpretation of the results of the basal metabolic test is the significance attached to figures reported only slightly above the limits of normal. It is a common observation to obtain at an initial test figures of from +15 to +35 which at a second or third rate-taking will be found well within the limits of normal. Obviously in such instances the earlier figures do not represent basal conditions and are usually caused by failure of the patient to completely relax. It is most important in the performance of this test that the patients be under basal conditions, otherwise the results are of no value. The candidates for this test are often nervous and apprehensive and hence at times are with difficulty at the first test brought under basal conditions. Ziegler and Levine⁶, Landis⁷, and Henry⁸ have demonstrated that mental un-

rest during the procedure can cause an elevated metabolism as high as +40. To overcome the various possibilities of error and to avoid accepting the results of a single test as confirmation of a diagnosis of thyroid toxicity, a safe rule to follow when the reported findings are elevated is to repeat the test until normal figures are obtained or until the rate reaches a stationary level. Figures reported up to +15 should be considered within the limits of normal especially in ambulatory patients⁹.

The following case histories illustrate the manner in which repeated metabolic studies will finally clear up the diagnosis.

Case IV A woman, aged 58, had suffered from pains in her legs for several months. A moderately severe grade of diabetes was present, requiring insulin. For some time there had been rather marked nervous and mental symptoms. Feeling that a thyroid adenoma might be the cause of her symptoms, a metabolic test was made. The rate was found to be +26, three days later +24, and on the next day +4. After eighteen months of insulin treatment the patient was found to be greatly improved in health, particularly in respect to the nervous and mental symptoms.

Case V A woman, aged 30, had complained of nervousness and rapid heart action for several weeks. There was no loss of weight, sensitiveness to heat or thyroid enlargement. An internist, feeling that a diagnosis of hyperthyroidism should be considered, ordered a metabolic study. The rate on December 14 was found to be +27, and one week later, +27. She was then admitted to the hospital for further study. Here the metabolic rate was found to be, on January 9, +37, on January 10, +26, and on January 17, +13, which is within the limits of normal. She was discharged somewhat improved with a diagnosis of a neurosis. A rate taken 6 months later gave a figure of +3, all symptoms were relieved.

and there had been a gain of 15 pounds in weight. It would have been very easy to have made the error of removing the thyroid here if repeated metabolic tests had not been made.

Case VI A nurse, aged 21, with previously good health, after taking over the responsibilities of a ward supervisor, developed fatigue, nervousness, rapid heart action, anorexia and some loss of weight. The possibility of the presence of hyperthyroidism was considered. The metabolic rate on May 3 was found to be +26, on May 8, +34, and after a brief rest from her duties the rate was found to be +11. Because of the presence of some nervous and gastric symptoms her vacation was extended for two months, after which she was feeling in the best of health and her weight had increased by 20 pounds. At this time the metabolic rate was found to be +8. Two years have now elapsed with no return of symptoms. Here again repeated metabolism tests cleared up the diagnosis and saved the patient from unnecessary surgery.

The question often arises whether or not hyperthyroidism is ever present when the metabolic rate is normal. The majority opinion, especially of those having extensive experience with the test, is that this is uncommon—perhaps even less common than the presence of syphilis when the Wassermann test is negative. One must be cautious of accepting relief from surgery as proof of the presence of hyperthyroidism. The neuropathic patient is commonly relieved at least temporarily by any surgical procedure but time will eventually bring out the same or a new train of symptoms. At times the removal of an adenomatous or nodular goiter will give marked relief in the presence of a normal metabolism. In such cases the mechanical relief must not be lost sight of and the normal metabolism may be explained by the taking of iodine or the presence of a

remission period so common in this type of struma. The so-called burned out toxic goiter usually has a normal or near normal rate, but shows extensive clinical evidence of damage due to long standing toxicity.

Hyperthyroidism for the most part is a well defined, yet often not easily diagnosed symptom complex. The most dependable symptoms are (1) definite loss of weight in the presence of a normal or increased food intake, (2) a persistent tachycardia of over 80, (3) a constant feeling of warmth or a sensitiveness to heat. On the other hand symptoms often associated with Graves' disease such as fatigue, sweating, tremor, transient rapid heart rate, choking sensations, loss of weight in the presence of anorexia and sub-normal food intake, nervousness and emotionalism are more often caused by functional disorders of the nervous system than by true thyroid disease. It should always be kept in mind when a goiter is present that nervous symptoms may at times be present and be unrelated to it.

Care should be exercised in diagnosing mild hyperthyroidism with metabolic rates of from +15 to +35 especially if of short duration. These cases should be kept under observation for a time and repeated metabolic studies made. Ultimately normal figures will be obtained in the great majority of these border line cases as is well illustrated in cases V and VI.

The presence of mental symptoms, hysterical seizures, fits of depression, crying spells and marked emotionalism should be a warning that one may not be dealing with thyroid disease. This is well illustrated in case III. Like-

wise marked chronicity of nervous symptoms, especially where there is a marked nervous or mental family tendency, is a factor against the diagnosis of thyroidism

Great caution should be exercised in making a diagnosis of hyperthyroidism in a patient under age 20. Because of the presence of a struma and certain nervous symptoms, the error is often made. The metabolism in this group is often found to be below normal pointing rather to a hypofunction of the thyroid. Surgery is rarely indicated and then only after most careful consideration of the diagnosis

SUMMARY

1 The term Graves' disease, because of its association with the thyroid gland, should be reserved for cases of hyperthyroidism

2 The large neurogenetic group

simulating hyperthyroidism and usually classified under the term Graves' disease should be designated by some other term to indicate its neuropathic origin and to avoid any association with the thyroid gland

3 The basal metabolism test is the most important factor in the diagnosis of hyperthyroidism, when properly performed and interpreted

4 The most dependable symptoms of hyperthyroidism are persistent tachycardia, loss of weight in the presence of a normal or increased food intake and a sensitiveness to heat.

5 Hyperthyroidism should be diagnosed with caution under the following conditions; in the presence of mental symptoms, when symptoms are mild and the metabolic rate is from +15 to +35, when there is marked chronicity of nervous symptoms and in cases under age 20

Hero Worship and the Propagation of Fallacies

(Lessons from the Lives of Jean Astruc and John Hunter)*†

By C S BUTLER, M D, F A C P, Captain, (M C), U S Navy,
U S Naval Hospital, Brooklyn, N Y

GABRIEL LeClerc in the year 1692 wrote a compend entitled "La Chirurgie Complete" which, according to Garrison went through eighteen editions. The fourth edition was translated into English in 1707, and we will quote part of the title-page of this because of its pleasing quaintness of diction "The Compleat Surgeon or the Whole Art of Surgery explain'd in a most familiar method. Containing an exact account of its principles and several parts, viz Of the bones, muscles, tumours, ulcers, and wounds, simple and complicated, or those by gun-shot, As also of Venereal Diseases, the Scurvy, Fractures, Luxations, and all sorts of Chirurgical Operations. To which is added a Chirurgical Dispensatory, shewing the manner how to prepare all such Medicines as are most necessary for a Surgeon, and particularly the Mercurial Panacea." This must have been a popular compendium of surgery for the students of those days both French and English. The delightful little book gives an excellent dis-

cussion of the venereal diseases, correct as to types with the omission of chancroid which was not defined until 1858. Gonorrhea or the "Chaudépisse" and its complications and syphilis, or the pox, were handled much as they are today. Indeed the treatment of these two diseases is about as effective as it was at the beginning of the twentieth century.

Jean Astruc (1684-1766), celebrated physician of Louis XV was so scholarly at the height of his career that few contemporaries dared oppose him. In addition to writing a critique upon certain parts of the Bible, he gained for himself a well-earned reputation as a literary physician at a time when medicine was emerging from Medievalism. Of his medical works, perhaps the most important was entitled "A Treatise of the Venereal Disease in Six Books." The Latin text of 1736 was translated into English the following year. It has never been understood even by his own countrymen how such a scholar as Astruc could lend himself to the propagation of so much that was fallacious in a single volume. As is well known, he contended that there was only *one* venereal disease and that this had been transferred from America to

*Read at the Annual Meeting of the American Society of Tropical Medicine, New Orleans, Louisiana, November 20th, 1931.

†Received for publication, November 2, 1931.

Europe by Columbus' ships. The whole force of his classical education was exerted to prove these two fallacies forty-four years after LeClerc's first edition, and though his writings were cried down by other scholars of the day, yet it is a matter of history that his work on "the venereal disease" has influenced medical thought and literature down to the present time. So much of an impression did he make upon the medical men of his time and succeeding generations that it requires only a perusal of the volume of John Hunter entitled "*A Treatise on the Venereal Disease*", published in 1786, to see that Hunter not only embraced Astruc's views, but actually the title for his own work. He accepted Astruc's interpretation of the venereal diseases in toto. He puts aside, however, the American origin of syphilis with a sentence, in which it appears that he does not care to consider this feature, though agreeing with Astruc as to the appearance of syphilis in Europe at a recent date.

As to the question of the viruses of gonorrhea and syphilis being the same, Hunter was so positive of the truth of this that in 1767, when he was 39 years of age, he inoculated himself with material from what was probably a urethral chancre though he thought it gonorrhoeal pus. Born in 1728, he died in 1793, and it was evident from his description of his own symptoms and from the write-up of Sir Everard Home on the course of the disease from which he died, that this inoculation influenced his entire future career. Hunter's first attack of angina pectoris occurred in 1773, just about six years after his unfortunate

inoculation. By 1785 he had progressed so far that generalized arteriosclerosis had extended to the point of producing cerebral symptoms, due to arteriolar spasm simulating the Adams-Stokes syndrome. Following a period of unconsciousness, he had twitchings of the muscles of the nose, face, lower jaw, and left arm. This was a fairly typical example of the syphilitic cerebral syndrome. By the year 1789 a type of oculomotor palsy had developed which was most likely syphilitic. Few histories are more pathetic than that of the devotion of this great man to a search for the facts about syphilis. The influence of Astruc, however, is so evident in his case that it needs only a perusal of the two volumes to see that Astruc's views held him captive. Hunter's works are among the great contributions to English medical literature. In turn his force and personality and practical knowledge won many generations of physicians who in turn accepted his word as law.

In a delightful study of the history of certain medical instruments Professor Logan Clendenen¹ describing the revolution which Schonlein and his students effected in the teaching of clinical medicine uses the following phrase: "Happy is that medical school which has on its faculty three or more intensely vivid clinical teachers who hate one another and despise their rival's methods and views. Stimulating is the mental atmosphere of such an establishment." Schonlein, Freirichs, Traube, and Wunderlich in a very brief period revolutionized clinical teaching and gave to medicine a proper estimate of thermometric de-

terminations in disease and of the importance of temperature curves in various infections. The brief history of these two groups shows the relative value of hero worship and of intellectual competition in the search for truth.

In 1816 another great French physician was at the height of his professional career, Doctor A. J. L. Jourdan. In that year he published in the "Journal Universel des Sciences Médicales" five articles entitled "Considerations Historiques et Critiques sur la Syphilis". Jourdan, like Astruc, was also a medical *litterateur*, but Astruc had some seventy-five years advantage in point of time. In these articles Jourdan completely disproves Astruc's ideas in regard to the origin of syphilis, and backs it up with incontrovertible evidence. This gem of medical literature was translated into English by Doctor R. LaRoche in 1823 and published in Philadelphia in that year. It has remained buried there for the past century. In 1826 Jourdan wrote his exhaustive treatise entitled "Traité Complet des Maladies Veneriennes", 2 volumes, Paris, in which he gives all the material concerning the subject under consideration which had come out in the first named publication. Opinions and facts we think quite modern were shown by this French scholar to extend well into the Dark Ages and in some cases into ancient times. While his views upon constitutional syphilis were incorrect, most of his work was sound. In spite of these and other more recent treatises showing the fallacies in Astruc's work, one of these fallacies goes merrily on and at the present

time is held by the majority of physicians of Europe and America. We refer to the American origin of syphilis which Astruc appropriated from Oviedo's book of 1525.

Coming back to Hunter, whose opinions were now considered as infallible, we find that he ventured to express positive views upon matters about which he knew little and to indulge in speculation in a way not calculated to advance a knowledge of medicine. We are speaking now of Hunter, the syphilographer. As a urologist, Hunter was years in advance of his time.

On pages 14 and 15 of his treatise, he attempts to show how "the venereal disease" was introduced into the South Seas. Calling upon the voyages of Captain Cook, who, as is well known, visited most of the island groups of the South Pacific between the years 1768 and 1779, he expressed the view that it was the French under Bougainville, 1766 to 1769, who first introduced the venereal disease into Otaheite (Tahiti) for although Cook visited Tahiti sometime in advance of Bougainville, Hunter convinces himself that it was Bougainville who introduced the venereal diseases into the Society group. As a matter of fact both the English and French fleets were important factors in spreading venereal diseases through the islands of the South Pacific. In connection with Hunter's statements in this regard, we will quote the views expressed by one or two modern writers upon tropical medicine. Manson-Bahr² expresses himself upon the origin of yaws in the following terms: "The home of yaws at the present day is within the true tropics, between

Capricorn and Cancer, its chief ravages are mainly confined to the old world, its distribution in the new (West Indies, Venezuela, Guianas, and Brazil) being directly due to the infamous influence of the slave trade. Thus has Fate decreed that the gift of syphilis from the new world to the old, consequent upon the Spanish Conquest, should be repaid in kind some hundred years later by the exportation of yaws from Africa by negro slaves." In "Tropical Diseases" by the same author³, occurs this sentence in connection with immunity in yaws: "Apparently saturation of a community with yaws virus produces a relative immunity to syphilis. On these grounds may be explained the apparently well authenticated fact that syphilis is *absent* amongst the Polynesians of Fiji, Tonga, and Samoa, in whom yaws is especially prevalent." Now it is axiomatic in the epidemiology of syphilis that there is no place on earth the white man has visited from which syphilis is *absent*, so that Manson-Bahr is but expressing the views of Astruc and Hunter, views of the middle of the eighteenth century, when making these statements in 1928 and 1929. Hunter's remarks upon the origin of "the venereal disease" in the South Sea Islands is but another example of the unscientific, not to say ungenerous, effort to "wish" syphilis off on the people of other races, efforts so common in the fifteenth and sixteenth centuries.

On pages 382 and 383 of the 1786 edition, Hunter speaks with assurance upon yaws. It appears that he saw only one case of this condition in the course of his career and upon this he

makes his positive statements. In this he reminds us very forcibly of certain "library authorities" on yaws at the present time. At this place in his treatise we find such assertions as the following: "Yaws have a regular progress after going through which they leave the constitution in a healthy state at least free from that disease. It being sufficient for the cure that the patient be in a state favorable to general health." This resembles very much some of the 1930 assertions emanating from Manila, that yaws is one of the easiest of all constitutional diseases to cure, assertions made in complacent disregard of the controverting experience of scores of tropical practitioners in other parts of the world. However, I think that Berkeley Hill's sentence about Hunter's *one* case of yaws proves the soundness of someone's belief in the emphasis of understatement. Here is Hill's sentence (Syphilis and Local Contagious Disorders, page 15): "John Hunter writing 'on diseases resembling the lues venerea, which have been mistaken for it', describes a case of yaws that was clearly syphilis, for the very reasons he advances to prove it could not have been that disease." Castellani and Chalmers⁴ writing upon yaws make the statement that the endemic home of yaws is in America and that Sydenham's statement that it is in Africa is not compatible with the facts as now known. "It must be remembered", they remark, "that the discovery of America led to a great many voyages in all directions, and we need not be surprised to find that Bontius in 1718 found the disease to be endemic in Java, Sumatra, and other

Dutch Colonies in the East Indies

In 1832 Bennet stated that it was endemic in the Tonga, Society, and Navigator Islands, while Koeniger believes that its introduction into the Samoan group was comparatively recent. It is therefore possible that it may have spread throughout the tropics from America, both in an easterly and westerly direction." Was it the white crews making the voyages "in all directions" that spread yaws to the Orient? Yaws is *not* a white man's disease. The date, 1832, is over 50 years after Bougainville and Cook. Thus do the authorities on tropical medicine differ very markedly on the geography of yaws and here they are accepting the views of the older writers who knew much less about the facts than we of the present.

There is no way of reconciling the diverse statements and opinions expressed by John Hunter and the others quoted with the facts as known about yaws. Such bizarre, fanciful statements are made by the "yaws experts" in all parts of their description of it from definition to treatment! These fanciful statements make of this condition what we have elsewhere spoken of as a medical monstrosity. The fallacies of these statements have been considered by many writers for all of the divisions of the description of this *impossible* entity. We should like to notice only one more of these inconsistencies having to do this time with the pathological side of the description of yaws. In an article entitled "Yaws, As Observed in Haiti", Doctor Howard Fox⁵ quotes from the laboratory report the following pathological differentiation. "Microscopic examina-

tion of early and late yaws showed an edematous verrucous plasmoma in which the infiltration was horizontally delimited below and was not intimately related to inflamed blood vessels, as in syphilis. Plasma cells were more succulent and larger than in syphilis, giant cells were rare and there was no productive inflammation of the blood vessels." Most of these statements have been disproven or properly evaluated by Choisser and others, but it seems that the pathologist here depends upon the relative "succulence" of the plasmoma cells to enable him to differentiate the histopathological picture of yaws from that of syphilis. One wonders if a "standard of succulence" might not be established in order to aid in such differentiation. The description of the histology of the yaws granuloma harks back to the erroneous conclusions of MacLeod⁶, who compared the framboesoma, *not* with its luetic reflected image, the condyloma and the circinate syphilid, but with the histological picture of syphilides in general. Moreover, MacLeod seems to have labored under the impression that framboesia did not affect the viscera. This is quite erroneous. At the present time there is a considerable amount of autopsy material from cases of Haitian treponematoses being studied in the Department of Pathology of the University of Michigan and it is hoped that this investigation will give us the facts about the histopathology of yaws.

In conclusion, we may say that the effect of the work of Astruc and Hunter upon our knowledge of the venereal diseases has been to confuse

rather than to clarify, to perpetuate fallacy rather than to uncover truth. A comparison of their careers with those of Schonlein, Frerichs, Traube, and Wunderlich leads to the conclusion that in advancing a knowledge of medicine it is better to have open intellectual combat than to have too much scholarship and too much hero worship. It has fallen to the speaker's lot to be unable to accept some of the

current views regarding yaws and syphilis. It is not a pleasant task to be an "image breaker" in this field. Carlyle did not treat of the "Hero as Physician." Had he done so, he might have found several candidates for Hero Worship in tropical medicine. It is our firm belief that when the blight of hero worship is eradicated from tropical medicine, the views of Hutchinson and of Jourdan will prevail.

Editorial

THE JOHN PHILLIPS MEMORIAL PRIZE

It is with very sincere pleasure, indeed, that announcement is made elsewhere in this issue, in the form of an excerpt from the Minutes of the December meeting of the Regents of the American College of Physicians, of the award of The John Phillips Memorial Prize to Doctor Oswald T Avery. This award is in recognition of the work of Dr Avery on the capsular polysaccharides of the pneumococci, leading to the production of an enzyme having a specific and selective action upon the Type III polysaccharide, both in the chemically pure state and as it

exists in the capsules of the living pneumococci. Further, Dr Avery has shown that mice, injected with an active preparation of the enzyme together with multiple lethal doses of a virulent culture of Type III pneumococcus, survive infection. The specific enzyme, by decomposing the capsular polysaccharide, apparently renders the infecting organism vulnerable to the defensive mechanisms of the animal body. Thus a new mode of attack upon the causal agencies in the infectious diseases is opened for experimental investigation.

THE LYMPHOID TISSUE CHANGES IN THE PRO- DROMAL STAGE OF MEASLES

In a paper which was not published until after his death, Warthin¹ described the occurrence of large multinucleate giant cells in the tonsils of four patients who subsequently developed measles. In each instance, as afterwards appeared, tonsillectomy had been performed from twenty-four to ninety-six hours before the appearance of the exanthem. So characteristic were the histopathological findings

that they were used successfully in the later cases of the series to predict the onset of measles before clinical evidence was available. One child was removed from an open ward and placed under contagious disease precautions on the strength of the pathological diagnosis alone, and the subsequent appearance of the eruption justified the confidence which the clinician had placed in the diagnosis made by the pathologist. The essential pathological lesion in the tonsils and pharyngeal mucosa in the prodromal stage of measles was found to be a subepithelial infiltration of multinucleate giant cells, lymphocytes and monocytes, with wandering of the giant cells into the mucosa and on to its surface. The germinal centers of the lymphoid

¹WARTHIN, ALDRED SCOTT. Occurrence of numerous large giant cells in the tonsils and pharyngeal mucosa in the prodromal stage of measles, *Arch of Path*, 1931, x1, 864-874.

follicles were found to show lymphoid exhaustion and here, also, numerous multinucleate giant cells were present. A cervical lymph node from one of these patients, examined after recovery from measles, showed no similar changes. That these changes are not confined to the tonsils and pharyngeal mucosa is evident from a recently reported observation of Herzberg.² On the fourth day after an appendectomy a child developed a rash on the face, body, and extremities, with Koplik spots, conjunctivitis and cough. A definite diagnosis of measles was made. In several of the lymph follicles of the appendix, but apparently in a sharply localized area only, there were found multinucleate giant cells. From the description and illustrations of these giant cells and the associated hyperplasia and lymphoid exhaustion of the germinal centers, it seems certain that Herzberg has found in the appendix during the prodromata of measles the same lesion which Warthin found to be pathognostic of the onset of this disease when seen in the pharyngeal mucosa and tonsils. This provides evi-

dence of a more general invasion of the lymphadenoid tissues during the onset of measles than had hitherto been demonstrated. It is to be hoped that others will search for these apparently highly significant histological changes when opportunity is presented.

PROGRAM OF THE SAN FRANCISCO MEETING

In the College News Notes section of this issue will be found the final program of both the General and the Clinical Meetings of the Sixteenth Annual Clinical Sessions of the American College of Physicians. Fellows and Guests expecting to attend will find it highly advantageous to observe the directions which are included having to do with transportation, reservations, and registration for Clinics and Demonstrations. In richness of material, breadth of interest and skill in arrangement, these programs give evidence, on the one hand, of the unselfish labors of those whose task it was to assemble them, and, on the other, of the great wealth of material for didactic and clinical medicine which San Francisco and its Pacific Coast neighbors possess. An unusually profitable meeting is in prospect for all who can attend.

Abstracts

The Detection and Estimation of Radium in Living Persons III The Normal Elimination of Radium By HERMAN SCHLUNDT and G FAILLA (Am Jr Roentgenol and Rad Therap, 1931, xxvi, 265-271)

Using as subjects two girls who had contracted radium poisoning during employment as dial painters during the period 1917 to 1919, the authors determined the rate of elimination of radium by determining the total quantity of radium present in each subject, as well as the quantity eliminated each day. The first of these values was arrived at by making gamma-ray measurements on the subjects by means of a standardized electrometer and adding to the value thus obtained the quantity of radium responsible for the radium emanation (radon) found present in the air expired. Combining all the experimental results, it appeared that the radium content of Subject A, twelve years after exposure, was 24 μg , and of Subject B, 14 μg . The quantity of radium removed day by day by excretion was determined by estimations, about 90 per cent of the amount eliminated being found in the feces. The total radium eliminated daily by Subject A amounted to 1161 μg , corresponding to a coefficient of daily elimination of 0.005 per cent. The total daily elimination of Subject B was 363 μg , giving a coefficient of daily elimination of 0.0026 per cent. Possible reasons for the difference in the coefficients for the two subjects are discussed. It is of interest that reduction by the process of natural decay of the element need not be considered practically in the case of radium stored in human body, for its half period is about 1600 years. The experiments reported show, therefore, that radium continues to be eliminated even twelve years after ingestion, although the rate of elimination is very slow. They also show that most of the radium eliminated is found in the feces. The results throw considerable doubt

upon the validity of the assumption that the stored radium is distributed uniformly throughout the skeleton.

Involvement of the Central Nervous System in a Case of Glandular Fever By SAMUEL H EPSTEIN, M D, and WILLIAM DAME-SHEK, M D (New England Jr Med, 1931, ccv, 1238-1241)

Severe headache, blurring of vision, photophobia, and general malaise had marked the onset of disease in a young man, 19 years old, who was admitted to the hospital in a stuporous condition. The spleen could be felt and there was a generalized enlargement of the lymph nodes. The total white blood cell count was 14,900 per cubic millimeter, with 63 per cent lymphocytes and 8 per cent monocytes. In all respects the morphology of the blood was typical of that occurring in infectious mononucleosis. Lumbar puncture yielded a clear, colorless fluid under normal pressure. On admission there were 34 white cells per cubic millimeter, chiefly lymphocytes. This number rose to 44 eight days later, but after that time gradually decreased, falling about proportionately with the decrease in white cells in the blood. Culture of the spinal fluid showed no growth and the Wassermann reaction was negative. The subsequent clinical course, resulting in complete recovery, served to rule out certain possibilities in the differential diagnosis, particularly acute lymphatic leukemia and tuberculous meningitis. It appears obvious that in this case the acute neurological condition and the general lymphoid hyperplasia with mononucleosis must be closely related. The nature of this relationship cannot be answered completely at present. The close parallelism between the cellular changes in the cerebrospinal fluid and the changes in the leukocyte count is significant. The simultaneous clinical recovery and the return to normal of the white blood cells indicate at least a temporal relationship so that it is not

unreasonable to suppose that the same infectious agent which caused the lymphoid hyperplasia also produced the central nervous system condition. Johansen has recently reported a similar case emphasizing the relationship between serous meningitis and infectious mononucleosis.

Renal Lesions in the Toxemias of Pregnancy By E. T. BELL, M.D. (The Am Jr Path, 1932, VIII, 1-41, 3 plates)

Twenty cases of toxemia of pregnancy were divided into five groups: (1) typical eclampsia with convulsions, (2) eclampsia without convulsions, (3) pre-eclampsia, (4) hyperemesis gravidarum, and (5) pregnancy in association with pre-existing renal disease. The pathological changes found in these patients at autopsy are detailed with special attention to the kidneys. In fatal cases of eclampsia and pre-eclampsia a characteristic glomerular lesion was found. The glomeruli were found to be slightly enlarged and the lumina of their capillaries narrowed. The decrease in size of the capillary lumina is caused chiefly by a marked thickening of the capillary basement membrane, but sometimes by an increase of endothelial cells. In one patient, who had had an attack of eclampsia seven years before, focal hyaline areas were found in the glomeruli with partial or complete glomerular obliteration and varying degrees of tubular atrophy. In one case of hyperemesis gravidarum, glomerular lesions were found like those of typical eclampsia. In three other cases the glomeruli were normal. A fatty liver without necroses is characteristic of this form of toxemia. When a woman with chronic renal disease becomes pregnant, there is usually an aggravation of all the nephritic symptoms. Chronic nephritics show no special tendency to develop gestation eclampsia.

The Influence of Solar Rays on Metabolism, With Special Reference to Sulphur and to Pellagra in Southern United States By JAMES H. SMITH, M.D. (Arch Int Med, 1931, XLVIII, 907-1063)

Sulphur in the form of cystine appears to exert a protective action against exposure to solar radiation in low forms of life. Its high concentration in the epidermal tissues

of higher animals suggests a possible protective action here also. Thus it appears that an adequate supply and a normal metabolism of sulphur exert a preventive influence against the pathologic effects of solar irradiation. Conversely, it is suggested that an inadequate supply of sulphur as cystine is an important cause of pellagra. Further, the distribution of pellagra and the variations in its prevalence and incidence suggest that solar irradiation, under certain abnormal conditions of nutrition, is an important factor in the etiology of pellagra, and that the reaction to solar rays not only is conditioned by the nutritive state, but depends on a state of the tissues determined by contrasts in degree and intensity of exposure during the annual cycle.

A Clinical Study of Myxedema in Michigan By H. H. RIECKER, M.D. (Jr Mich State Med Soc, 1931, XXX, 831-835)

From a study of the geographical distribution of 64 cases of myxedema in the series studied, and in comparison with the usual clinical experience in other regions, it is concluded that this disease is more common in the Great Lakes goiter district than in non-goitrous regions. In the series studied, 75 per cent of the patients were female, and 34 of the 64 were in the age-group 41-60. In 40 per cent the basal metabolic rate was between 15 per cent and 25 per cent below normal. The most common presenting symptom of the patients in this group was weakness. One organ or system was frequently noted to present outstanding signs or symptoms. Anemia, skin lesions, mental and cardiac complaints, and digestive disturbances illustrated this point. Obesity emphasizes rather than submerges the characteristics of the disease.

Über vorübergehende Hemiplegien durch Nicotin [Transitory Hemiplegia Due to Nicotine] By F. KULBS (Klin Wochenschr, 1931, X, 2159-2161)

In four cases, three men whose ages were between 21 and 38 years and a woman 40 years old, transitory paralytic phenomena appeared. In the three men these consisted of hemiplegia and speech disturbances. In the woman there was a motor aphasia. These

disturbances had been preceded by evidences of lessened functional capacity as shown by ease of fatigue, or by headache, paresthesia and dizziness. In all cases there had been gross overuse of tobacco, evidence of which was found in lymphocytosis, elevated basal metabolic rates and marked nervous and vasomotor irritability. Since there was a complete restoration to normal in all cases within a short time of the interdiction of

the use of tobacco, it is believed that the hemiplegic phenomena were due to a vasoconstrictor effect of tobacco. Acute fatigue, hereditary factors and syphilis could all be excluded with certainty as etiological agents. This observation may be a significant contribution in respect to that group of cases which shows hemiplegia clinically, without anatomical changes adequate to explain its occurrence.

Reviews

Recent Advances in Allergy (Asthma, Hay-Fever, Eczema, Migraine, etc.) By GEORGE W. BRAY, M.B., C.M. (Sydney) Asthma Research Scholar, The Hospital for Sick Children, Great Ormond Street, London. With foreword by ARTHUR F. HURST, M.A., M.D. (Oxon), F.R.C.P., Senior Physician, Guy's Hospital, Chairman Medical Advisory Committee, Asthma Research Council of Great Britain. 432 pages, 98 illustrations, including 4 colored plates. P. Blakiston's Son & Co., Inc., 1012 Walnut St., Philadelphia, 1931. Price, \$3.50.

The author's two years of research in asthma at the Hospital for Sick Children have evidently given him a wide experience with allergic disease. He reviews the important theories and surveys the large field of experimental work. Brief historical sketches are also interspersed. He discusses heredity and the endocrines as factors in the causation of allergy. The more usual manifestations of allergy, as asthma, hay-fever, eczema, urticaria and angioneurotic edema are taken up in some detail. Numerous other conditions, such as dermatitis venenata, migraine, epilepsy, muco-membranous colic, vaccine therapy, drugs, serum reactions, hypersensitiveness to insects, the effects of molds and fungi, are discussed as to their known and possible relation to allergy. Addition and elimination diets are given. This book gives a fairly complete treatment of the subject, written in a compact form, and in a clear, easily read style. Unfortunately, all pollination data are for the British Isles. So significant is geographical distribution

and pollination chronology in the botanical aspect of allergy, that it would be well to have an American edition when reprinting is undertaken.

The Human Voice By LEON FELDERMAN, M.D., x + 301 pages, 22 figures. Henry Holt and Company, New York City, 1931. Price, \$2.50.

There is probably no medical book more difficult to write than that which endeavors to expound medical matters to lay readers. And there is no book which requires any greater degree of precision and accuracy in statement, for it must be assumed that the group for whom it is intended will be altogether unable critically to evaluate it. It is stated in the book under review that it is intended to bridge the difficulties between the vocal teacher and his pupil and that "a sincere effort has been made to strip discussions of technical terms and to write in a language familiar to all." In regard to the sincerity of the author and the innocence of the publishers there can be no question. The introduction of such terms as [in the actual spellings used] *archi pallium*, *kinaesthetic*, *laryngo-periskop*, *pharmacotoxic*, *lancelating*, *streptococcic hemolyticus*, and *non-memolytic*, leaves some doubt as to whether the language is understandable by all. More serious are actual errors in fact, stated or implied. Some of these are of an extraordinary nature. For instance, in regard to the possible spread of syphilis by unsanitary lunch rooms and soda fountains, it is stated that "Hordes of flies gather, ready to carry the *larvae* from one place to another, and the vicious circle of

contagion is maintained" The combination of syphilis as a fly-borne disease and of the Treponema as a larva in the same sentence compels a pause even from one who is accustomed to grading examination papers The author is evidently a believer in the efficacy of maternal impressions in the etiology of disease, for he lists among the causes of stammering, a fright or a profound disappointment experienced by the mother during the prenatal period Scientific medicine has been striving for several decades to release the human mind from the bondage of such erroneous ideas Thus the reviewer is forced to the conclusion that to be both useful and safe this book requires extensive revision

Confessio Medici By STEPHEN PAGET, F R C S, Late Vice Chairman Research Defense Society xi + 158 pages The Macmillan Company, New York City, 1931 Price, \$2.00

Again these charming essays are made available for the general medical reader Published in 1908, this reissue brings them to a new generation of physicians They can never grow old for they are of the medical life itself Vocation, Hospital Life, An Essay for Students, A Good Example, Practice, The Discipline of Practice, The Spirit of Practice, Wreaths and Crosses of Practice, Retirement, and The Very End are the titles of the series, with a Preface and an

Epilogue Since each essay is complete in itself this is a book to be picked up in the moment of leisure when the available time is short or to be taken along as a companion on a journey The publishers are to be commended for bringing out this new issue

Guide to Radiologic Diagnosis in Heart Disease Prepared with the Aid of the Committee on Research of the Heart Committee By GEZA NEMET, M D 33 pages, 31 figures New York Tuberculosis and Health Association, Inc, 386 Fourth Avenue, New York City, 1931 Price, 35 cents

A concise system for the interpretation of roentgenograms of the heart is set forth in the interest of securing suitable technical procedures and a more uniform nomenclature

Criteria for the Interpretation of Electrocardiograms Prepared with the Aid of the Committee on Research of the Heart Committee By ARTHUR C DEGRAFF, M D, 19 pages, 42 figures New York Tuberculosis and Health Association, Inc, 386 Fourth Avenue, New York City, 1931 Price, 35 cents

This is a concise statement of criteria in electrocardiography arranged by diagnoses and by terminology

College News Notes

THE PHILLIPS MEMORIAL PRIZE

The following announcement is an excerpt from the minutes of the meeting of the Board of Regents held December 20, 1931

"Dr Means, Chairman of the Phillips Memorial Prize Committee, reported that his Committee had proceeded according to the revised regulations adopted by the Board of Regents, which were, briefly, that the Committee seek a candidate for the prize rather than invite submission of manuscripts as had been done the year before. After discussing the procedure of his Committee, he presented the name of Dr O T Avery, Hospital of the Rockefeller Institute for Medical Research, New York City, with the recommendation to the President that the prize be awarded to Dr Avery for the series of studies upon the pneumococcus in which he has played a leading rôle, beginning with the discovery of the type specific soluble capsular polysaccharides and culminating in the discovery of a bacterium which produces an enzyme which splits the polysaccharides of Type III pneumococcus in vitro, thus rendering it susceptible to phagocytosis and thereby protecting the animals which are infected with it'

"This recommendation was adopted unanimously

"President White stated that if it could be arranged, Dr Avery's presentation should be made at the time of the Convocation, and preceding the Presidential Address, to which the Board agreed"

Acknowledgement is made of the receipt of gifts to the College Library of publications by members, as follows

Dr Henry Daspit (Fellow), New Orleans, La, 1 autographed copy, No 54, "Matas Birthday Volume",

Dr Hyman I Goldstein (Associate), Camden, N J, 1 reprint,

Dr H Beckett Lang (Fellow), Marcy, N Y, 5 reprints,

Dr William D Reid (Fellow), Boston, Mass, 3 reprints,

Dr Walter M Simpson (Fellow), Dayton, Ohio, 1 reprint, "Aldred Scott Warthin",

Dr Charles T Way (Fellow), Cleveland, Ohio, 1 reprint,

American College of Surgeons, 1 copy of 1932 Directory

Dr Frank Smithies (Master), Chicago, Ill, presented a medical clinic before the Mahoning County Medical Society at the Youngstown, Ohio, Hospital, October 20, and on the evening of the same date, addressed the Mahoning County Medical Society on "Gastric Hemorrhage"

Dr Louis Faugeres Bishop (Fellow), New York City, as one of the Trustees of Rutgers University, has been assigned to the Governing Committee of the New Jersey College of Pharmacy, Newark, N J. The College will give a four year course leading to the degree of B S in Pharmacy. The course will cover the requirements of the American Medical Association of a pre-medical course for those students who may wish later to study medicine.

Dr D N Kremer (Fellow), Philadelphia, Pa, addressed the Bay Ridge Medical Society, Brooklyn, N Y, December 8, on "Obesity and Its Management"

Dr I S Kahn (Fellow), San Antonio, Texas, in collaboration with Dr B F Stout of San Antonio, read a paper entitled, "The Practical Value of the Cytological Examination of the Nasal Smear in the Differential Diagnosis Between Allergy and Infection (Preliminary Report)," at the recent meeting of the Southern Medical Association

Dr W J Stapleton, Jr (Fellow), Detroit, Mich, gave a lecture on "Medicine in Art" before the Detroit Medical Club on December 17, 1931

Dr Stapleton also gave a radio talk on the subject, "Periodic Health Examination" over Station WWJ, January 5, 1932

Dr Ralph Pemberton (Fellow), Philadelphia, Pa, recently gave a paper on "Arthritis" at the Annual Clinic of the Sectional Meeting of the Michigan State Medical Society at Jackson, Mich

Dr Horace W Soper (Fellow), St Louis, Mo, read a paper on "Roentgen Diagnosis of Lesions in the Small Intestine," with x-ray illustrations, before the Radiological Society of North America on December 1, 1931

Medical Clinics by the following Fellows of the College were published in the December Number of the Hahnemannian Monthly

Dr G Harlan Wells, Philadelphia, "Trichiniasis",

Dr Carl V Vischer, Philadelphia, "Bronchial Asthma",

Dr Donald R Ferguson, Philadelphia, "Chronic Valvular Heart Disease of Rheumatic Origin with Passive Congestion"

Dr John R Vonachen (Fellow), Peoria, Ill, was recently elected President of the Peoria County Medical Society

Dr Ada E Schweitzer (Fellow), Indianapolis, Ind, Child Hygiene Director of the Indiana State Board of Health, has recently issued several interesting and helpful bulletins, promoting infant and child hygiene and health in that state

Dr Clyde L Cummer (Fellow), Cleveland, Ohio, has recently published the third edition of "Manual of Clinical and Laboratory Methods," through Lea & Febiger, Philadelphia

Dr Cummer is the author of an article entitled, "Lupus Erythematosus in Infancy and Childhood," Archives of Dermatology

and Syphilology, 1931, XLIV, 999-1032 This article was originally read at the meeting of the American Dermatological Association at Toronto during 1931.

Dr Robert E Ramsay (Fellow), Pasadena, Calif, has recently been elected President of the Pasadena Branch of the Los Angeles Medical Association

Dr Joseph H Bryan (Fellow), Asbury Park, N J, has been elected President of the Alumni Association of the New York Homeopathic Medical College and Flower Hospital Dr Bryan was a member of the graduating class of 1890 of that institution

Dr W G Herrman (Fellow), Asbury Park, N J, read a paper entitled "Varieties of Pulmonary Spirochetosis" before the American Roentgen Ray Society, at their last meeting in Atlantic City Dr Herrman also published an article entitled, "Uterine Hemorrhage Radiologically Considered," in a recent issue of the Journal of the New Jersey State Medical Society

Dr Harold S Davidson (Fellow), Atlantic City, N J, has been elected President of the Atlantic County Medical Society for the year 1932

WHO MAY REGISTER—

- (a) All members of the American College of Physicians in good standing for 1932
- (b) All newly-elected members
- (c) Members of the San Francisco County Medical Society, without registration fee, upon presentation of their 1932 membership cards in their local society
- (d) Medical students pursuing courses at the University of California Medical School and the Stanford University School of Medicine, upon presentation of matriculation cards or other evidence of registration at these institutions
- (e) House Officers of the hospitals participating in the program
- (f) Members of the Medical Corps of the Public Services of the United States and Canada, without fee, upon presentation of evidence of their appointments
- (g) Qualified physicians who may wish to attend this Session as visitors. Such visiting guests shall pay a registration fee of \$15.00, and shall be entitled to one year's subscription to "Annals of Internal Medicine" (in which the proceedings will be published), included within said fee

REGISTRATION BLANKS FOR ALL SPECIAL CLINICS AND DEMONSTRATIONS are sent to members with the official program. Guests may secure a copy of the program by request to the Executive Secretary.

TRANSPORTATION to and from the San Francisco Clinical Session has been arranged on the Identification Certificate plan of fare and half fare. With the exception of the southeast territory, this reduced rate applies for return by diversified routes. In the southeast territory, members must return by the same as the going route, in order to secure the fare and half fare rate. For diverse return routes in the southeast, the fare will be one and three-fifths of the one way tariff.

Reduced fares apply not only to members, but also to dependent members of their families.

Before purchasing tickets, members must secure from the Executive Secretary an Identification Certificate, to entitle them to the reduced fares.

In general, tickets will be sold from March 26 to April 8, with a return limit of thirty days in addition to date of sale. The fare for children of five, and under twelve, years of age will be one-half of the round trip fare for adults. Children under five years of age free when accompanied by parent or guardian. Stop-overs will be allowed at all stations within final limit on either going or return trip, or both, on application to conductors.

All tickets must be validated by a special railroad agent at the San Francisco headquarters from April 4 to 8.

Official itinerary of special train and post-convention tour. Arrangements have been made for a special train from the East to San Francisco, over the Baltimore & Ohio, Chicago & Northwestern, Union Pacific and Southern Pacific Railroads. Following the Session it will proceed over the Southern Pacific, Santa Fe and Baltimore & Ohio railroads back East, according to the following schedule, which has been arranged for the greater comfort and pleasure of members en route. A special booklet has been distributed to every member.

Those not desiring to take the post-convention tour may return East by regular train over the same or diversified routes from San Francisco, in a period of from four to five days, depending on the route selected. They may, of course, go out with the special train and return by other routes, either railroad, steamship by way of the Panama Canal, or by air. There is a sailing over the Panama Pacific Line from Los Angeles, on April 11, arriving in New York April 25. Full details will be furnished by the Executive Secretary upon request.

Air travel by way of the United Air Lines to the convention may be arranged at the following rates, and in the time indicated:

New York to San Francisco	\$160 00	31 hours
Chicago to San Francisco	115 00	23¼ hours
Omaha to San Francisco	95 76	18½ hours
Seattle to San Francisco	43 98	7 hours
Los Angeles to San Francisco	18 95	3 hours

Similar rates from 137 cities in 30 states

THE GENERAL BUSINESS MEETING OF THE COLLEGE will be held in San Francisco on Thursday, April 7, at 4 30 P M, immediately following the general scientific program of the afternoon. All Masters and Fellows of the College are urged to be present. There will be the election of Officers, Regents and Governors, the reports of the Treasurer and the Executive Secretary, and the induction to office of the new President, Dr Francis M Pottenger, Monrovia, Calif.

THE CONVOCATION OF THE COLLEGE for the induction of newly-elected Fellows will take place Wednesday evening, April 6, at 8 00 P M, in the Gold Ballroom of the Palace Hotel.

After the induction of the new members, Dr O T Avery, of New York City, will deliver an address on "The Rôle of Specific Carbohydrates in Pneumococcus Infection and Immunity," following which he will be awarded the John Phillips Memorial Prize by the President, Dr S Marx White. After this President White will deliver the annual presidential address.

An informal reception to new members will follow immediately after the program.

THE ANNUAL BANQUET OF THE COLLEGE will be held at 7 30 o'clock, Thursday evening, April 7, at the Palace Hotel. All physicians of San Francisco and vicinity and visitors attending the Session are invited, with their ladies, by the members of the College and its Officers to attend this Banquet. A special program will be announced later. Tickets for the Banquet must be purchased at the Registration or Information Bureaus before 10 o'clock, Thursday morning.

ENTERTAINMENT FOR VISITING LADIES. A special program of entertainment for the wives, daughters and friends of attending physicians is being arranged. The ladies are most cordially invited to come to California, and to register with the Ladies' Entertainment Committee.

THE COMMERCIAL EXHIBIT will be located near the Registration Headquarters at the Palace Hotel. The Exhibit will be diversified, consisting of medical literature and texts, pharmaceutical products, apparatus and appliances, special foods, etc. These exhibits are of real scientific value, and every member should definitely arrange to inspect all of them.

FINAL PROGRAM GENERAL SESSIONS

San Francisco, Calif—April 4-8, 1932

To provide for the General Sessions a program representative of the best and most advanced work of the year has been more difficult than in some of the previous meetings. The time required for travel by some of the most distant Fellows not as yet air-minded may have proved to be occasionally a deterrent but a survey will show in spite of the difficulties a program of extraordinary breadth and wealth. One circumstance more than compensates for the distances involved for many of the Fellows and Guests. The response to invitations on the part of men in the West and on the Coast has been prompt and satisfactory. A strong and active membership in the West has been faithful and persistent in attendance wherever the College met but, naturally, has been at a numerical disadvantage in the construction of programs. To bring together a large amount of the work of this group provided an opportunity eagerly seized. The large number of new names of active workers is in line with the policies followed in constructing this program. The wealth of material submitted has made selection difficult. The program is an unusually full one.

Special attention may be called to certain features.

1 *Diseases of the kidney* receive consideration in three papers in the opening Session. These papers are practical, of the most lively interest and by men known to every student of the problem.

2 *The liver* is studied from both the experimental and practical standpoint as a part of the program on Tuesday afternoon.

3 On Tuesday evening a strong scientific program will include some of the outstanding work of the *Hooper Foundation* by its director. The work on *pulmonary tuberculosis* will include a summary of the ten years work at the *Lymanhurst School for Tuberculous Children*, and the relation of the paranasal sinuses to general medicine will be discussed by a long time student of this problem. The *motion picture demonstration* of the factors in the defense of the respiratory mucosa should not be missed.

4 A series of papers on Wednesday afternoon covers some very live topics on the blood vessels and, in addition to papers of practical clinical interest, includes an expo-

sition of the *physics and physiology of arteriosclerosis and hypertension* New facts about *epilepsy* are discussed and the Director of the Hooper Foundation closes the afternoon with an address on the protective measures of the State of California against *food poisoning*

5 *The endocrines* do not go unheralded Sober masters of some of their mysteries will discuss them on Thursday afternoon For this year the ever-ready heart seems crowded somewhat into the background but *circulatory failure, cardiac complications and the electrocardiogram* are found on the Thursday afternoon program

6 Symposia have been replaced for the most part by groups of papers as outlined above One symposium of outstanding significance atones for the numerical lack The Friday afternoon symposium on the *autonomic nervous system* brings together the most authoritative students of its anatomy, physiology and clinical considerations, together with a résumé of its most recent investigator, the surgeon It is planned so that the physician may have before him all of the recent great advances in knowledge of this field It is believed that this symposium alone will make attendance at this Sixteenth Annual Session worth while The Friday afternoon program closes with three papers of extraordinary interest following the symposium

The history of medicine is of interest to so large a proportion of the membership that it receives attention again in the General Session A part of the Monday evening program is given to papers by two delightful exponents of the history of our profession *Medicine in Utopia* and the first aphorism of Hippocrates will be treated in a manner no one would wish to miss

Those interested in the history of medicine will find opportunities in the clinic program unsurpassed at any previous session The San Francisco Committee has made special provision of papers and exhibits which should call out a large attendance These will be found in the clinic program

An intermission has been provided every afternoon except Monday On that day everyone is fresh and the varied nature of the program makes an intermission less needed In addition it has been possible to visit the exhibits during the morning and the noon hour The intermissions will be properly signalled and it is hoped that every member will respond promptly in attending the programs as they are renewed The program this year is rich and varied and it will be necessary to keep to schedule at every moment

The importance of visiting the exhibits cannot be over-stressed

OPENING GENERAL SESSION

Monday, April 4, 1932, 2 00 P M

Gold Ballroom, Palace Hotel

1 Addresses of Welcome

Robert Gordon Sproul, President of the University of California
Robert E. Swain, President of Stanford University
Langley Porter, Dean of the University of California Medical School
William Ophuls, Dean of the Stanford University Medical School
Junius B. Harris, President of the California Medical Association
Alson R. Kilgore, President of the San Francisco County Medical Society

2 Reply to Addresses of Welcome

S. Marx White,* President of the American College of Physicians

3 Pathological Differentiations in Bright's Disease

Jean Oliver, Brooklyn, N. Y.

(Guest)

4 Clinical Differentiations in Bright's Disease

Thomas Addis,* San Francisco, Calif

- 5 The Relation of Nephrosis to Nephritis
E T Bell, Minneapolis, Minn
(Guest)
- 6 Clinical Aspects of Gastric Secretion
Arthur L Bloomfield,* San Francisco, Calif
- 7 Practical Applications of Recent Discoveries in the Field of Gastro-intestinal
Physiology
Walter C Alvarez,* Rochester, Minn

SECOND GENERAL SESSION

Monday Evening, April 4, 1932, 8 00 P M

Gold Ballroom, Palace Hotel

Presiding Officer

Wm J Kerr,* San Francisco, Calif

-
- 1 The Clinical Study of the Atrophic Tongue
Wm S Middleton,* Madison, Wis
 - 2 Medicine in Utopia
Richard E Scammon, Minneapolis, Minn
Dean of Medical Sciences of the University of Minnesota
(Guest)
 - 3 The First Aphorism of Hippocrates
George Dock,* Pasadena, Calif
 - 4 The Modern Hospital—Its Relationship to the Physician
B W Black, Oakland, Calif
Medical Director of the Highland Hospital of Alameda County
(Guest)

THIRD GENERAL SESSION

Tuesday Afternoon, April 5, 1932, 2 00 P M

Gold Ballroom, Palace Hotel

Presiding Officer

Walter L Bierring,* Des Moines, Ia

-
- 1 Some Aspects of Bile Function
Carl L A Schmidt, Berkeley, Calif
(Guest)
 - 2 The Effect of the Administration of Glucose and Insulin on the Glycogen Content
of Normal and Experimentally Damaged Livers
T L Althausen, San Francisco, Calif
(Guest)
 - 3 Further Observations on Primary Carcinoma of the Liver in Chinese
G F Strong, Vancouver, B C
(Guest)
H H Pitts, Vancouver, B C
(Guest)
 - 4 Hepatic Pathology in Exophthalmic Goiter and the Graves Constitution
Carl V Weller,* Ann Arbor, Mich
 - 5 The Element of Error in the Diagnosis of Jaundiced Patients—A Review of 500
Cases Verified at Operation or Autopsy
George B Eusterman,* Rochester, Minn

- 6 Asthenia—Clinical Types and Principles of Therapy.
George Morris Piersol,* Philadelphia, Pa
Edward L. Bortz,* Philadelphia, Pa

INTERMISSION

Visit the Exhibits!

- 7 The Newer Aspects of Parodontosis (Pyorrhea)
Hermann Becks, San Francisco, Calif
(Guest)
- 8 The Rôle of Bacteria in Asthma
Robert L. Benson, Portland, Ore
(Guest)
- 9 Rocky Mountain Spotted Fever
G. Gill Richards,* Salt Lake City, Utah
- 10 The Significance of Fever
Hobert A. Reimann, Minneapolis, Minn
(Guest)
- 11 Poisonous Spider Bites
Emil Bogen, Olive View, Calif
(Guest)
- 12 Studies on the Chemotherapy of Amebiasis
Chauncey D. Leake, San Francisco, Calif
(Guest)

FOURTH GENERAL SESSION

Tuesday Evening, April 5, 1932, 8 00 P M

Gold Ballroom, Palace Hotel

Presiding Officer

J. C. Meakins,* Montreal, Que

- 1 Recent Studies in Equine Encephalomyelitis Discussion and Motion Picture Films
Karl F. Meyer, San Francisco, Calif
Director of the George Williams Hooper Foundation
(Guest)
- 2 Ten Years at the Lymanhurst School for Tuberculous Children
J. Arthur Myers,* Minneapolis, Minn
- 3 Treatment of Cavities in Pulmonary Tuberculosis
LeRoy S. Peters,* Albuquerque, N. M.
- 4 Atelectasis and Tuberculosis
W. Warner Watkins,* Phoenix, Ariz
H. P. Mills,* Phoenix, Ariz
Fred G. Holmes,* Phoenix, Ariz
- 5 The Paranasal Sinus Problem in the Practice of Medicine
Arthur D. Dunn,* Omaha, Nebr
- 6 Mechanical Factors in the Defense of the Respiratory Mucosa A Motion Picture
Demonstration
Anderson Hilding, Rochester, Minn
(Guest)

FIFTH GENERAL SESSION

Wednesday Afternoon, April 6, 1932, 2 00 P M

Gold Ballroom, Palace Hotel

Presiding Officer

George Morris Piersol,* Philadelphia, Pa

- 1 The Treatment of Raynaud's Disease by Repeated Exposure to Cold
Wm J Kerr,* San Francisco, Calif
- 2 Physics and Physiology of Arteriosclerosis and Hypertension
Carl J Wiggers,* Cleveland, Ohio
- 3 Aortic Hypoplasia as a Cause of Death
Edgar T Herrmann,* St Paul, Minn
- 4 Clinical Diagnosis of Pulmonary Arteriosclerosis
Henry L Ulrich,* Minneapolis, Minn
- 5 Primary (Essential) Hypertension—A Clinical and Morphological Study of Three
Hundred and Seventy-five Cases
Francis D Murphy,* Milwaukee, Wis
- 6 Hypertension—A Follow-up Study After Eight to Fifteen Years
J N Blackford,* Seattle, Wash

INTERMISSION

Visit the Exhibits!

- 7 Demonstration and Use of the Radiotherm in Disease of the Circulation
C F Tenney,* New York, N Y
- 8 Experimental Bases for Vaccine Treatment of Chronic Arthritis with Summary
of Results of Treatment
B J Clawson, Minneapolis, Minn
(Guest)
- 9 Metabolic Abnormalities in Obesity
Russell Wilder, Rochester, Minn
(Guest)
- 10 Some Recent Observations Regarding the Nature of Epilepsy
Irvine McQuarrie, Minneapolis, Minn
(Guest)
- 11 The Present Status of the Ketogenic Diet in the Treatment of Epilepsy
D Schuyler Pulford,* Woodland, Calif
- 12 The Protective Measures of the State of California Against Food Poisoning
Karl F Meyer, San Francisco, Calif
Director of the George Williams Hooper Foundation
(Guest)

Wednesday Evening, 8 00 P M

Gold Ballroom, Palace Hotel

CONVOCATION OF THE COLLEGE

The general profession and the general public are cordially invited No special admission tickets are required Evening dress is recommended

- 1 Convocation Ceremony
- 2 Address The Rôle of Specific Carbohydrates in Pneumococcus Infection and Immunity
O T Avery, New York, N Y

*F A C P

- 3 Presentation of the John Phillips Memorial Prize
- 4 Presidential Address
S Marx White, Minneapolis, Minn

Reception to New Members

An informal reception to new members will follow immediately after the Convocation exercises. Newly inducted Fellows should sign the Roster and secure their Fellowship Certificates following the Convocation program.

SIXTH GENERAL SESSION

Thursday Afternoon, April 7, 1932, 2 00 P M

Gold Ballroom, Palace Hotel

Presiding Officer

Charles G Jennings,* Detroit, Mich

- 1 The Biological and Clinical Importance of Ovary-Stimulating Substances
C Frederic Fluhmann, San Francisco, Calif
(Guest)
- 2 Animal Experiments with Adrenal Cortical Extracts
C L Connor, San Francisco, Calif
(Guest)
J L Carr, San Francisco, Calif
(Guest)
- 3 A Chemical Study of the Suprarenal Gland
E C Kendall, Rochester, Minn
(Guest)
- 4 The Clinical Syndromes of Adrenal Hyperfunction Illustrated by Lantern Slides
Hans Lissner,* San Francisco, Calif
- 5 Various Clinical Syndromes Associated with Diseases of the Suprarenal Glands
L R Rowntree,* Rochester, Minn

INTERMISSION

Visit the Exhibits

- 6 Modern Muscle Physiology and Circulatory Failure
Jonathan C Meakins,* Montreal, Que
- 7 The Cardiac Complications of Funnel-breast
James Gray Carr,* Evanston, Ill
- 8 A Study of 800 Abnormal Electrocardiograms and Associated Clinical Findings
Martin A Mortensen,* Battle Creek, Mich

The Annual General Business Meeting of the College will be held immediately after the last paper. All Masters and Fellows are urged to be present. Official reports from the Executive Secretary and Treasurer will be read, new Officers, Regents and Governors will be elected, and the President-Elect Dr Francis M Pottenger, will be inducted into office.

Thursday Evening, 7 30 P M
Palace Hotel

THE ANNUAL BANQUET OF THE COLLEGE

Toastmaster Dr Arthur L Bloomfield,* Professor of Medicine, Stanford University Medical School
Address "A Great Country Doctor"
Dr Charles J Singer, University of London, London, England

FINAL GENERAL SESSION

Friday Afternoon, April 8, 1932, 2 00 P M

Gold Ballroom, Palace Hotel

Presiding Officer

Francis M Pottenger,* Monrovia, Calif

SYMPOSIUM ON THE AUTONOMIC NERVOUS SYSTEM

- 1 Anatomy
 - a General Considerations
 - b Distribution to Skeletal Muscles and Blood Vessels

S W Ranson, Chicago, Ill
(Guest)
- 2 The Functions of the Autonomic Nervous System and Its Chemical Agents
Walter B Cannon, Boston, Mass
(Guest)
- 3 Clinical Considerations Control of Heart, Lungs and Bronchi
Harry L. Alexander, St Louis, Mo
(Guest)
- 4 Control of Blood Pressure and Renal Function
Hilding Berglund, Minneapolis, Minn
(Guest)

INTERMISSION

Visit the Exhibits!

- 5 Control of Gastro-intestinal Tract
A J Carlson,* Chicago, Ill
- 6 The Results of Sympathectomy in the Treatment of Peripheral Vascular Diseases,
Hirschsprung's Disease and Cord Bladder
Alfred W Adson, Rochester, Minn
(Guest)
- 7 Moving Picture Film "Behaviour of Animals Deprived of the Sympathetic System"
Walter B Cannon, Boston, Mass
(Guest)
- 8 Leukopenia Its Clinical Significance, with Special Reference to Aleukemic Leukemia
and Leukemoid Conditions
Stacy R Mettier,* San Francisco, Calif
- 9 The Action of Benzol, Roentgen Ray and Radium on the Blood and Blood-forming
Organs
Edwin E Osgood, Portland, Ore
(Guest)
- 10 Some Important Factors in Edema Formation
Eaton M MacKay, San Diego, Calif
(Guest)

SPECIAL CLINICS AND DEMONSTRATIONS

Clinics and demonstrations will be held in the forenoons from 9 00 to 12 00 daily,
Tuesday to Friday, inclusive

Tickets will be required for each and every one of the special clinics, ward rounds
and demonstrations The co-operation of everyone in securing his clinic tickets will
assist greatly in distributing the attendance according to the capacity of each program
It is self-evident that a ward round arranged for twenty-five will lose its value for all if

*F A C P

forty or fifty are present Ticket registration naturally is the only effective method of keeping the attendance within the capacities indicated

To all members of the College, registration blanks for the clinics and demonstrations have been distributed with the final program

A-I

Tuesday, April 5, 1932

UNIVERSITY OF CALIFORNIA HOSPITAL
(Parnassus and Third Avenues)
Toland Hall, First Floor
(Capacity—167)

- 9 00- 9 45 Mistakes in the Treatment of Heart Disease
James B Herrick, Chicago, Ill
- 9 45-10 30 Venous Pressure Determinations as Related to the Diagnosis and Treatment of Cardiac Decompensation
William S Middleton, Madison, Wis
- 10 30-11 00 Medical Clinic on Cardiovascular Diseases
William J Kerr
- 11 00-11 30 Medical Clinic on Cardiovascular Diseases
John J Sampson
- 11 30-12 00 Medical Clinic on Cardiovascular Diseases
Eugene S Kilgore

A-II

UNIVERSITY OF CALIFORNIA HOSPITAL
(Parnassus and Third Avenues)
Room 310, Third Floor
(Capacity—35)
Medical Clinic on Tuberculosis

- 9 00-10 00 Manifestations of Clinical Tuberculosis in the Adult
F M Pottenger, Monrovia, Calif
- 10 00-11 00 Juvenile Tuberculosis
Chesley Bush
- 11 00-12 00 Tuberculosis and Tuberculous Infections Among Nurses
Sidney J Shipman and Elizabeth A Davis

A-III

UNIVERSITY OF CALIFORNIA HOSPITAL
(Parnassus and Third Avenues)
Ward A, Fourth Floor
(Capacity—15)

- 9 00-10 00 Ward Rounds Cases of Cholecystitis
John M Blackford, Seattle, Wash
- 10 00-11 00 Medical Aspects
Fred H Kruse
- 11 00-12 00 Surgical Aspects
H Glenn Bell

Tuesday, April 5, 1932 (Continued)

Cutaneous Manifestations of Systemic Disease*†

By UDO J WILE, M D , *Ann Arbor, Michigan*

MORE than a half a century has elapsed since cutaneous medicine became established as a recognized special field. The development of specialties in general has come about rather slowly, receiving initiative from the great epochs of modern medical science, notably the rational pathology of the Virchow school and the application to the theory and practice of medicine of the principles of modern bacteriology and immunity.

Dermatology may be said in some respects to have had an unfortunate and precipitous birth. It did not develop gradually but was rather abruptly established as a result of the classification of dermatoses based upon pure morphologic characteristics by the early founders of the Vienna school. This has resulted in the development of a cumbersome, awkward, and somewhat irrational nomenclature.

The early interpretation of pure morphologic pictures as these occur in the skin led away from, rather than

toward, the concept of general morbid processes. The natural result of this schism from the domain of general medicine was the development of a field with its own peculiar pathology, and with an ever-widening breach between its confines and the pathologic processes which affect other systems.

A science based upon such superficial characteristics could not long endure as such. The last two decades, therefore, have seen a great change in the interpretation of disease processes in the skin. The recognition of the integument as an organ of fundamental importance in the general physiology of the body, its function as a vast heat-regulating mechanism, as an excretory and secretory organ, and more latterly its recognition in the important biophysical and biochemical activities of the organism, are rapidly aligning disease conditions in the skin with the general pathologic state of the individual. Each year sees more and more so-called essential dermatoses proved and accepted as the cutaneous reflections of systemic morbid processes.

Cutaneous medicine therefore concerns itself with the concept of the skin and its appendages, as a complex organ which graphically reflects systemic disease processes in a vast variety of what might be termed *reac-*

†Read at a Stated Meeting of the New York Academy of Medicine, December 3, 1931. Received for publication, December 30, 1931.

tions Conversely, it also serves as an excellent yardstick whereby may be evaluated and measured standards of good health

The so-called essential skin diseases have in the course of the last few years been narrowed down to local infections, both bacterial and mycotic, and to a few benign and malignant growths. The several unexplained inflammatory diseases in the skin such as lichen planus and psoriasis, may in our ignorance still be regarded as peculiar to the integument. The ultimate elucidation of their nature, however, may well show them to be the manifestations of a general rather than a local pathologic condition

It is manifestly impossible to enumerate or to discuss in detail all of the various skin manifestations of systemic disease. It would, I think, be far better to emphasize the theme suggested by taking two texts: first, the subject of focal infection in its relation to cutaneous disorders; and, second, the intimate relation of the skin to the group of so-called lymphoblastomatous diseases

Among the many theories elaborated to explain the phenomena of morbid processes, none has seemed at first glance so attractive, so readily applicable to many diseases, as that of bacterial foci from which systemic infections take place. Following, as it did, in logical sequence, the identification of specific microbes as causative agents in the production of disease, and the subsequent knowledge of bacterial sepsis, it is easily comprehensible why the theory of focal infection should have been readily applied to hitherto unknown etiologic entities

That focal infection has passed from a scientific theory to a proved principle cannot be gainsaid. The work of Billings, Rosenow, Holman and many others in this country and abroad has established beyond peradventure that its application to certain disease processes fulfils all scientific postulates. However, it must also be admitted that, like uric acid, the theory of focal infection has had woven about its application as much of fiction as of truth.

There is a basic misconception and rather widely current confusion in the minds of many who have written and spoken on this subject, between the terms, focus of infection and focal infection. The two are frequently loosely and synonymously applied in both writing and discussion, when in fact they should be sharply differentiated.

Billings described a focus of infection as a circumscribed area of tissue infected with pathogenic organisms. Holman has pointed out, therefore, that any condition resulting from the systemic dissemination of bacteria from the source or focus becomes a focal infection. It is therefore self-evident that focal infection results from foci of infection and the two terms, although related sequentially, have different identities and must not be confused.

Perhaps the simplest example of proven focus and consequent focal dissemination is the chancre of syphilis, here we have a nidus of pathogenic organisms leading to more or less rapid dissemination and to remote morbid processes in the skin, viscera, and mucous membranes, thus representing admirably a focal infective process.

It seems quite natural that, in the

ten or more years since Billings' first paper on focal infection, the theory should have found favor among dermatologists, and an earnest effort should have been made to apply it to our many obscure etiological problems. When the initial wave of enthusiasm passed, it was found as in other advances in medical science, that something new had been added to our knowledge of the causation of disease, but much was left over to be explained by other theories. It is safe to state that at some time or other almost every etiologically obscure dermatosis has been said to result from a focus of infection, but only a few have stood the rigid scrutiny of scientific accuracy and have been established as of such origin.

With the clear-cut definition of a focus of infection as a nidus of pathogenic organisms, and of focal infection as the expression of systemic invasion by these organisms, very rigid criteria should be applied to a disease, together with convincing experimental evidence, before it may be accepted as an example of a focal infective process. In by far the majority of examples in cutaneous medicine, where focal infection has been suggested as the cause of symptoms, the case has been made on suggestive criteria and on clinical data. Thus, one observer with a series of cases of, let us say, alopecia areata, in which dental caries has co-existed, expressed the opinion that the latter as foci caused the former. His view was perhaps strengthened by the clinical observation that the alopecia disappeared after removal of the alleged foci. I shall hope to show later that while such evidence is perhaps suggestive or presumptive, it lacks scientific

accuracy and does not sufficiently support accepted postulates for cause and effect in disease.

At some time or other the following conditions have been considered to be due to foci, and therefore examples of focal infective processes: urticaria, urticaria pigmentosa, eczema, the erythema multiforme group, cutaneous tuberculosis and the tuberculides, hemorrhage, petechiæ, purpura hemorrhagica, herpes zoster, pemphigus, dermatitis herpetiformis, lupus erythematosus, keratosis blenorrhagica, and many others.

It now appears that in a few cases focal infection adequately explains certain cutaneous diseases in which up to now, to the best of my knowledge, that cause was not suggested for them. Such are the trichophytides, sporotrichosis, tularemia, and probably vaccinia and certain of the contagious exanthems.

It might be well at this time to apply rigid scientific criteria to the above groups, and to see to what extent focal infection is proven in one group, presumptive or likely in a second, and unlikely or improbable in the third.

In the proven group stand out syphilis, sporotrichosis and tularemia with their portals of entry in an injury, cases of systemic blastomycosis, the petechial and hemorrhagic lesions of bacterial sepsis, the trichophytides, scarlet fever, vaccinia, and the many extraordinary mutation forms of skin tuberculosis, including the sarcoid of Boeck, the deep tuberculosis of the hypoderm, and many of the so-called tuberculides. It may well be argued that systemic or blood-borne tubercle bacilli are difficult to determine, and that with all the evidence not at hand in every case, it

would seem improper, for example, to class lupus vulgaris in its many clinical forms, sarcoid tumor, lupus miliaris, and lichen scrofulosorum as examples of tubercle implantation from a remote focus. Admitting the validity of this argument, it is nevertheless true that the overwhelming preponderance of opinion favors the view that these are endogenous blood- or lymph-borne infections, and the weight of clinical evidence, together with some experimental proof, supports this view.

When we come to the tuberculides, however, we face a group of conditions which in part fit in with the concept of focal infections, and in part do not. It seems to be accepted that certain tuberculides are actually hematogenous tuberculous lesions. Bacilli have at times, with difficulty to be sure, been demonstrated, or occasionally animal inoculation has shown the lesions to contain bacilli. Others, on the other hand, are widely if not generally accepted as evidence of tissue changes due to tubercle toxin liberated from a tuberculous focus. To include such a group, providing the hypothesis of their nature is correct, in the class of focal infections, would necessitate a wider interpretation of our theory than we postulated at the outset.

In the interest of scientific accuracy, therefore, it would seem wiser to limit the term focal infection to those conditions in which systemic dissemination of pathogenic organisms occurs, and to place the group of toxic tissue reactions from remote foci, in a class which might properly be called *focal irritative processes*.

Following the researches of Jadasohn, Bloch, and their students, we may

now place in the group of proven focal infections the generalized dermatoses due to the hematogenous dissemination of mycelia and spores, originating in such local lesions as the kerionic ringworm. To these lesions the name of trichophytides has been given. The identification of this group and the demonstration of the entity as a systemic infection is a scientific achievement of considerable importance.

The petechial hemorrhages and purpura which are seen in the skin incident to bacterial endocarditis and to general sepsis, also fulfill the postulates of focal infections as do the rose spots of typhoid fever.

Scarlet fever is, of course, as good an example as is syphilis of a focal infection, if we accept the throat as the portal of entry of the streptococcus which produces the septic erythema. The weight of evidence also supports the view of a focal infection for the other contagious exanthems as well. Until we know more about the smallpox virus and the infectious agents of measles and chickenpox, however, we must place the entire group aside from scarlet fever and vaccinia as presumptive but not yet proven cases.

Sporotrichosis and tularemia are strikingly similar in their mode of onset as starting with lymph-borne infections, which occasionally develop septic manifestations. Both conform admirably to the criteria of focal infective processes.

Yaws in all probability fulfills the conditions of a focal infection, but until its epidemic character and method of transmission are better known, it is best not to include it in the proven focal infectious group at this time.

Although Rosenow has shown bacteria in some of the lesions of erythema multiforme, notably in erythema nodosum, and demonstrated similar strains in the tonsils and elsewhere, I do not believe the evidence at this time is sufficiently convincing to place this very large and varied group of cutaneous reactions with the proved cases of focal infection. The weight of clinical evidence, to be sure, in cases such as erythema nodosum in association with rheumatic fever, points to bacterial dissemination. However, it seems quite likely that many forms of erythema multiforme, perhaps the majority, are toxic rather than microbic processes. Many, indeed, very definitely are to be referred to such causes as foreign protein and drug reactions, thus establishing for them other etiologic factors than infective foci. While for the entire erythema multiforme group, foci of infection, therefore, as a cause do not fit, in isolated cases we may occasionally be dealing with hematogenous bacterial dissemination.

Toxins rather than infective organisms explain even more readily the urticaria group of dermatoses. These at one time may be due to local toxic irritations and at others to systemic intoxications, as from enteric protein sensitization or from toxins associated with gall bladder and hepatic disease. While frequent clinical evidence supports the view of foci of infection as the cause of urticaria, the local manifestation is never an evidence of systemic sepsis. It is a *focal irritative* rather than a focal infective process.

Herpes zoster is another disease probably definitely specific and due to an infective focus. The remote lesions

on the skin, however, can very properly be regarded as focal irritative rather than focal infective sequelæ. The immunity usually conferred by herpes zoster, moreover, does not fit in with the ordinary history of a focal infective condition where recurrence and chronicity are the rule. It stands out, however, as an admirable example of a change in a remote portion of the body dependent upon a focus of irritation.

A disease which may at some time be shown to be a focal infection, in which the evidence thus far is supported only by clinical evidence, is pityriasis rosea. The frequency of an initial plaque in this disease and the sudden explosion of satellite lesions support the view that we are dealing with systemic dissemination of an infectious agent from a primary plaque. My own experiments with this disease, extending over five years, while inconclusive, strengthen my belief that a specific blood-borne infectious agent is its cause.

Alopecia areata has been supported by many as an example of a focal infective disease. It is certainly true that the removal of carious and abscessed teeth has frequently resulted in the cure of this condition. Likewise, the uncovering of visual difficulties, sinus infection, and other foci of infection or irritation in the head, has resulted in spontaneous cure of the baldness. There is to my knowledge, however, no direct experimental evidence to show that alopecia areata can, in the strictest sense of the word, be a focal infection. If the preponderant number of cases cleared up upon removal of infectious foci, which in fact does not occur, the disease could at most be

placed, like herpes zoster, in the group of *focal irritative* processes

Many of our deductions as to the focal infective character of a disease are based first, upon the establishment of a focus of infection, and, second, upon the disappearance of the general process after the removal of the alleged focus. Both hypotheses are open to criticism. Most individuals can be shown to have some demonstrable focus of infection in the teeth, tonsils, gall bladder, appendix, prostate, or elsewhere. The finding of a focus is, therefore, only suggestive. Thus, if a tuberculous focus were found in a lymph node or tonsil in the presence of a cutaneous tuberculosis, the case would at once suggest the relationship between the two conditions, which might, however, be difficult of actual proof.

The clearing up of a systemic condition or of a dermatosis upon the removal of a focus of infection, moreover, has importance where bacteriologic proof is lacking, only when it occurs with great regularity, and only when other causes cannot operate to produce the same condition. Under these circumstances, focal infection may be assumed, but its ultimate proof still requires the demonstration of a pathogenic organism in both cause and result.

Where occasional cure of a dermatosis occurs upon removal of a focus, it is more than likely that this results from the relief of inhibitory forces which such a focus may exercise on general conditions, or it may be a response to general well being, resulting from the removal of the focus. These factors will explain the cases of lupus

erythematosus and of dermatitis herpetiformis, which occasionally clear up rapidly upon removal of infected foci. In both of these conditions the weight of evidence is against their being true focal infective processes.

It may properly be pointed out that occasionally the removal of a focus which, without doubt, is the causative factor of a dermatosis, is not followed by involution or even improvement in the focal infection. The demonstration and removal, for example, of a tuberculous lymph gland in the neck would effect little, if any, change in a resulting patch of lupus vulgaris, although it might well be a preventive measure against the development of new lesions. Irreparable tissue damage due to hematogenous germ dissemination cannot be followed by restitution when the source of the infection is laid bare and removed.

In conclusion, it may be emphasized that foci of infection play either a causal or a casual rôle in the etiology of many dermatoses, or their presence may have nothing whatever to do with the disease in question. Where the foci are *causal*, we are dealing with true focal infection as determined by blood-borne dissemination of the pathogenic organism from the focus to the satellite lesion. This occurs in a proven fashion in syphilis, cutaneous tuberculosis, certain tuberculides, the trichophytides, sporotrichosis, tularemia, systemic blastomycosis, vaccinia, and scarlet fever. A *casual* relationship occurs between foci and certain dermatoses with such frequency as to merit notice, and possibly to constitute a contributory etiologic factor in such conditions as erythema multiforme,

dermatitis herpetiformis, and alopecia areata

Finally, to the focal infective processes might well be added a group in which foci of infection play a direct rôle in the causation of satellite cutaneous lesions, in which pathogenic organisms are not present, but in which the tissue damage is apparently due to a toxic process. This occurs in herpes zoster, in some of the so-called toxituberculides, in many of the multiforme erythemas, and occasionally in urticaria. This group might properly be referred to as *focal imitative* processes.

THE LYMPHOBLASTOMA GROUP

During the past twenty years I have had a most unusual opportunity of studying a very large number of cases of what formerly were termed the lymphadenoses of the skin. In this connection I have been singularly fortunate in the exchange of views with my late colleague, Waithin, who throughout his active life contributed much to the pathology of these conditions. In 1929 there were reported from my clinic by Keim twenty cases of various clinical types, of which ten came to autopsy. A great diversity of opinion exists as to the proper classification of diseases of the hemopoietic system. Those which are frequently found in the skin and occasionally occur there before their demonstration in other parts of the body are leukemia, both myeloid and lymphatic, lymphosarcoma, Hodgkin's disease, and granuloma fungoides. From our studies of this group of diseases we have come to the belief that genetically they are closely related, occasionally occurring

as combined pictures or changing from one clinical form to another.

From the clinical standpoint the most frequent cutaneous manifestation of the so-called lymphoblastomas occurs as a persistent scaling erythroderma. So frequently is a true lymphadenosis ushered in by a universal scaling dermatitis that the chronicity of this condition should always lead to suspicion of its grave nature. The condition may occur with or without changes in the circulating blood stream. In the majority of cases these are absent at the outset and develop only later in the course of the disease. In a few of our cases marked lymphocytic deviations in the blood occurred only shortly before death. In the large majority of cases a marked lymphadenitis is present, though not usually developing until the disease has been present in the skin for some months. I have, however, seen a few cases in which there was general lymphatic enlargement preceding the development of the erythroderma. Of greatest diagnostic import in determining the lymphoblastomatous nature of an erythroderma is the early biopsy. Even in the very early period the picture is quite characteristic—an infiltrate of lymphoblastic cells occurring in the upper portion of the corium either in clumps or as a sharp band-like infiltrate quite similar in its architecture to that seen in lichen planus. The biopsy of the lymph glands shows enormous hyperplasia and the same type of lymphoblastic cells as are seen in the skin. In two cases of an unusual type of cutaneous lymphatic leukemia I have seen an ordinary exfoliative dermatitis, unassociated with lymphadenitis and

with no unusual blood picture, entirely remit for several months, then reappear with associated lymph gland involvement, and finally remain in a state of chronic cutaneous lymphadenosis with the blood changes of a chronic lymphatic leukemia. In one case of cutaneous leukemia with marked changes in both the blood and lymph glands, spontaneous recovery took place after four years of observation, during which time the patient on several occasions was considered dangerously ill. Since this observation I have seen spontaneous recovery in a second similar case.*

In myeloid leukemia the cutaneous manifestations are considerably more rare. Quite apart from the cutaneous hemorrhages and purpura, one occasionally sees tumors of varying size and density, more particularly occurring on the face. Their appearance on the skin very occasionally antedates or is coincident with the first symptoms which lead to an examination of the blood and the establishment of the diagnosis. The tumors are pure myeloid in structure, and many exist only as transitory cutaneous manifestations of the disease. I have seen one universal type in which large tumors of a purplish-red color appeared all over the body, some of which ulcerated. The resemblance of this type of case to the entity, *mycosis fungoides*, is quite striking.

In Hodgkin's disease one may recognize on the skin the so-called essential types of eruptions. These take the

form of definite nodules. The architecture of the latter conforms exactly to that of the pathologic picture seen in the lymph glands. The so-called non-specific lesions occurring in Hodgkin's disease take the form of prurigo-like nodules and excoriations and pigmentation. These are alleged to be toxic reactions rather than examples of true cutaneous Hodgkin's disease.

In at least one case, however, in which prurigo-like nodules occurred, I was able to demonstrate in the nodules very definite pathologic architecture typical of the disease.

The pigmentation seen in Hodgkin's disease is sometimes of a very bizarre nature. I have at present under observation a young man who was admitted for an ex-foliate dermatitis which rapidly cleared up on topical remedies. He returned to the hospital less than a month ago with a zone or band of deep brownish pigment extending around the waist and onto the upper portion of the thighs. There was also hyperpigmentation of the axillæ and sufficient thickening of the skin to suggest at least, a diagnosis of *acanthosis nigricans*—a pigmentary disorder discovered by Pollitzer many years ago and shown by him to be a frequent accompaniment of abdominal neoplasm. In addition to the pigmentation there was marked enlargement of the inguinal and axillary lymph nodes. A biopsy taken from these and from the overlying thickened skin showed typical early Hodgkin's disease.

With regard to lymphosarcoma, the cutaneous manifestations are extremely varied. One may have, as in leukemia, a scaly erythroderma, apparently benign at the outset and leading to

*Since this article was written the first patient has returned to the hospital with a relapse of the skin condition and with glandular enlargement, after a remission lasting over four years. (Author)

the diagnosis of simple exfoliative dermatitis from one cause or another. Subsequently a marked enlargement of the lymph nodes leads to the suspicion of the lymphoblastomatous nature of the eruption, and the biopsy, both skin and lymph node, readily establishes a diagnosis of small or large round-celled sarcoma. In the late stages of this condition actual metastatic nodes in the skin may occur in large numbers in various parts of the body. In other cases lymphosarcomatous nodes may appear in various parts of the otherwise normal appearing skin, to be followed at a later time by the generalized involvement of the lymph nodes. The picture of the erythrodermatous type is indistinguishable clinically from leukemia and from occasional cases of Hodgkin's disease.

I have before referred to the occasional combination pictures which are seen in these various conditions. So closely may they simulate each other that a clinical diagnosis must on occasion be changed from time to time during the course of the disease. Two cases will serve to illustrate this point. In one, definite lymphosarcomatous nodes were removed from the skin of a young boy who at the time showed little or no change in his blood. He later showed severe hemorrhages into the skin and hemorrhages from his mucous membranes, following which he developed a rapidly fulminating type of lymphatic leukemia from which he died. A second case which I still have under observation is that of an elderly man with multiple lymphosarcomatous nodes in the skin and lymph glands in whose blood at this time there are changes suggesting leukemia.

Many years ago there was demonstrated before the Dermatological Section of the Academy (New York) a patient in whom at the time it was believed both leukemia and granuloma fungoides were present. The case which I cited before of a young boy who died of myeloid leukemia in whose skin a large number of large ulcerative nodules occurred is, I believe, the analogue of this condition.

An interesting question arises in connection with those cases of lymphoblastoma in which a scaly erythroderma of an innocent type antedates the more serious phase of the disease. The suggestion in this type of case is that the cutaneous insult may be a primary factor in the activation of the lymphadenosis. In cases biopsied during the early period there may be no suggestion of a lymphoblastomatous infiltrate. While the majority of the cases are undoubtedly lymphadenoses from the outset, it is nevertheless a tenable hypothesis that in a few cases at least the lymphadenosis may be secondary to a prolonged skin insult. The analogy, at least, is present as regards occasional infection and acute lymphatic leukemia.

My own studies have convinced me that the lymphadenoses are reflected in the skin in three different ways. First and perhaps more rarely one may find in the incidence of lymphadenotic blood pictures, the cutaneous expressions as infiltrations and tumors, together with hyperpigmentation. These are true metastatic lesions. Second one finds pictures in which the cutaneous lymphadenotic infiltrations antedate the chronic involvement of the blood and lymph glands. In this group are found large numbers of cases of exfoliative

dermatitis of great chronicity, as well as isolated tumors and infiltrations. The third group includes particularly scaly erythrodermas and occasionally also localized infiltrations in which transitory deviations from the normal are found in the blood stream, together with characteristic hyperplastic changes in the lymph nodes. In this group occasional recovery may take place with complete restitution even after several months or years. In such cases I believe the skin pathology rather than reflecting systemic changes, may by continuous insult act as a causative factor in the production of secondary lymphadenotic changes which simulate closely the typical primary cases.

The group of lymphoblastomas illustrate admirably the cutaneous manifestations of systemic disease. They represent a very small although impor-

tant group which serves merely as a text upon which to elaborate the theme under discussion. One might with equal profit, if the time permitted, discuss the cutaneous manifestations of glycosuria, the unique changes in the skin incident to the disorders of fat metabolism such as occur in xanthoma, the atrophic changes of arteriosclerosis and senility, the remarkable changes in the integument with endocrinous dysfunctions, and the subject of the skin as a reflector of emotional states. These, and many others, could each be taken as a text to illustrate that, apart from its protective function, its thermostatic control, and its secretory and excretory functions, the skin admirably reflects and intimately takes part in many, if not most, of the morbid processes of the body.

Malignant Thymoma

of Reticulum-Cell Type With Pressure on the Left Lung, Trachea, Esophagus, Left Phrenic and Left Recurrent Laryngeal Nerves, and With Metastases to the Glands of the Left Side of the Neck; Importance of Biopsy for Differential Diagnosis of Cervical Lymphadenopathies*†

By LEWELLYS F BARKER, M D , F A C P , *Baltimore, Md*

THE patient selected by Professor Pincoffs to be discussed by me this afternoon illustrates very well not only the importance of making a general diagnostic survey, but also the great diagnostic help that may be derived from bioptic examination of a lymph gland when there is enlargement of the glands in the neck. Though we make it a rule to select, ordinarily, for demonstration at these clinics, cases of the more frequently encountered maladies of interest to the general practitioner, we are breaking that rule today in order to show you one of the rarer pathological states that offer certain difficulties in exact diagnosis.

CLINICAL HISTORY

The patient, Thomas M., a white huckster, aged 40, was admitted to Ward G of this hospital (service of Dr Harry M Stein) on October 27, 1931, complaining of hoarseness, cough, pain and swelling of the left neck, and loss of weight.

Present Illness About three months ago

*Clinic to physicians at the University of Maryland, November 19, 1931

†Received for publication, November 24, 1931

the patient picked up a heavy basket of fruit and, under the strain, suddenly felt a rather severe pain in the left neck. This pain disappeared, however, when he set the basket down. He was surprised when placing his hand upon the region in which he felt the pain to find a lump in the left neck. At about the same time he began to cough and to raise some sputum (without blood), he noticed also that his voice was becoming hoarse. One week after lifting the weight, he noticed that he was having pains radiating from the lump in the neck into the chest, and these gradually grew worse. He applied to the hospital dispensary for examination, and, after several visits and an x-ray examination of the chest, it was supposed that he had tuberculosis of the left upper lobe and of the lymph glands of the neck and he was sent to the tuberculosis department of the City Hospitals for treatment, though one of the examiners in the dispensary felt confident, even before x-ray examination of the thorax, that there was a tumor mass in the mediastinum. As no tubercle bacilli could, however, be found in the sputum on repeated examinations at the City Hospitals, a lymph gland was excised from the posterior triangle of the neck for diagnostic purposes, it was found to be non-tuberculous and it was thought to be sarcomatous. The patient was discharged by Dr Charles C Habliston and told to return to the dispensary here for further observation and for radiotherapy. As he continued to

lose weight and to remain hoarse, he was admitted to Ward G on October 27th

Previous History Except for measles in childhood and an attack of gonorrhea fifteen years ago, the patient has always been healthy. He has worked at various jobs. He apparently has never taken enough food for he has always been below ideal weight. He smoked one package of cigarettes a day up to the time of the present illness, and it was his custom to drink one quart of whiskey per week until seven or eight months ago. There has been no excess in the use of tea and coffee and he has not made use of drugs until needed for relief of pains in the present illness.

Family History The patient is married and his wife and two children are well. The family history has no bearing upon the patient's condition.

Physical Examination The patient's height is five feet, three inches, and his weight is 111 pounds, so he is a little more than fifteen pounds under calculated ideal weight. Since admission to the hospital, his temperature has varied between 99.4° on admission and 101.6° as a maximum. His pulse rate has varied from 80 to 110, and his respiratory rate from 20 to 25 per minute. He is of asthenic habitus.

In the head, no abnormal findings were observed except marked dental caries, gingivitis and a little hyperemia of the pharynx. No tumor masses could be made out in the nose or throat. The nasal septum was slightly deflected to the left. The voice was very hoarse and of low pitch.

In the neck, the thyroid was not enlarged. There was no tracheal tug. The trachea was displaced to the right and in the left supraclavicular fossa was a mass of rather soft lymph glands, more or less matted together (figure 1). The glands along the edge of the sternomastoid muscle were also enlarged on the left side. In the right side of the neck there was a wen about the size of a walnut.

The thorax was long and thin and the epigastric angle acute. There was some dilatation of the veins in the front of the left thorax and in the left side of the neck, the left half of the chest looked somewhat flatter than the right.

On respiration, there was distinct lag and lessened movement of the whole left chest as compared with the right and, on palpation, there was greater vocal fremitus over the right lung than over the left. On percussion, there was marked retrosternal dullness, and flatness over the left upper lobe, both in front and behind, the dullness extending behind downward to the level of the spine of the third thoracic vertebra and in front down to the fourth intercostal space and some four cm lateralward from the left parasternal line. On auscultation, aside from occasional sibilant and sonorous râles in both lungs, nothing was made out except relative suppression of the breath sounds in the left upper lobe, probably due to atelectasis. No pleural friction was heard.

The heart seemed to be of approximately normal size and there were no heart murmurs.

The abdomen was retracted and the liver was palpable one or two fingerbreadths below the costal margin. The tip of the spleen could not be felt.

Examinations of the nervous system (except for evidences of pressure on certain intra-thoracic nerves) were entirely negative and the psyche was clear.

Laboratory Tests *Sputum* Mucopurulent. No tubercle bacilli. No blood. Many streptococci.

Blood RBC, 3,970,000 to 4,340,000, on different counts. Hemoglobin, 80 per cent on admission, since reduced to 55 per cent. White cell count has varied between 11,800 and 15,280. Differential count: Polymorphonuclears, 75 per cent to 78 per cent, small mononuclears, 18 per cent to 23 per cent, large mononuclears and transitionals, 7 per cent to 11 per cent. Wassermann and Kolmer reactions, negative.

Urine Specific gravity, 1010 to 1015, negative for albumin and sugar, an occasional cast seen, no pus cells, occasional red blood corpuscle present, phthalein output 75 per cent in two hours.

Röntgenological Report (Dr Henry J Walton) Mediastinal tumor extending into the left side of the chest, situated more anteriorly than posteriorly. Atelectasis of the upper lobe of the left lung. Elevation and fixation of the left diaphragm. Dislocation

of the esophagus and trachea to the right with some narrowing of the lumen of the esophagus. Heart small and apparently rotated. Slight hypertrophic osteoarthritis of the thoracolumbar spine. Sacralization of fifth lumbar vertebra. No evidence of tumor metastases in the bones. (Figure 2)

Reports of Specialists *Nose and Throat examination (Dr. Looper)* Paralysis of the left arytenoid and complete paralysis of the left vocal cord, probably due to pressure on the left recurrent laryngeal nerve.

Biopsy of Cervical Lymph Gland On request of the internist, the hospital surgeon, Dr. Shipley, removed a lymph gland from the left side of the neck for microscopic examination. The histological study was made

by Dr. Hugh R. Spencer who made the following report:

"Capsule of lymph gland intact. On section, node is grayish white and appears to be cellular. One small area is yellowish and necrotic. On microscopic examination, the lymphoid tissue is replaced by actively growing tumor cells, which vary in morphology, some of them being round and others polyhedral, while those in relation to the blood vessels are somewhat columnar in shape and lie at right angles to the vessel walls. Many of the nuclei are hyperchromatic and mitotic figures are numerous. The blood vessels are poorly formed and, in some areas, tumor cells are in direct contact with the blood. There is some alveolation of the tumor but,

FIG. 1. The mass of lymph glands in the left supraclavicular fossa is visible, as well as the scar following the removal of a gland for histological examination. The small mass in the right side of the neck is a sebaceous cyst. The dilatation of the veins below the left clavicle can be seen.

in general, the arrangement is perivascular

"Impression The tumor is a sarcoma of the reticulum cell type, different from the usual type of reticulum cell lymphosarcoma in the arrangement of cells and in the vascularity of the tumor The thymus gland should be considered as the probable site of the primary tumor"

Course in the Hospital The patient's general condition has been closely watched by the interne, Dr M Cohen, and it has not undergone any marked change during his three-weeks' stay in the hospital The blood pressure has continued low, varying between 86 and 106 systolic and between 48 and 68 diastolic The secondary anemia has been increasing so that the hemoglobin is now down to 55 per cent The patient is holding his weight very well and has a fairly

good appetite He still tires very easily on exertion and has some pain in the left neck and in the upper chest

DISCUSSION OF THE CLINICAL FINDINGS

The Mediastinal Mass This space-occupying mass in the upper anterior mediastinum is causing pressure upon the left bronchus and left upper lobe, which has resulted in atelectasis There may be some actual infiltration of the lobe by the tumor mass The situation of the mass points to the thymus gland as a source of the pressure rather than to the lymph glands at the

FIG 2 Roentgenogram of the chest

root of the left lung There is no evidence that the mass is a substernal thyroid This mass has dislocated the trachea to the right and has caused pressure upon the esophagus It has also pressed upon the left recurrent laryngeal nerve, causing paralysis of the left vocal cord It has compressed the left phrenic nerve and has caused paralysis of the left half of the diaphragm Whether the tachycardia is due to pressure upon the vagus with partial loss of vagal inhibition is not certain

It is evident that we are not dealing with a simple hyperplasia of the thymus but with a true tumor growth

The Cervical Lymphadenopathy
You will recall that the patient's first symptom was pain in the left neck and the finding of a swelling in that region On examination at the hospital dispensary, and, later, in the hospital itself, the swollen neck was found to depend upon enlargement of the supraclavicular lymph glands and of the lymph glands along the sternocleidomastoid muscle One of these was removed by biopsy at the City Hospitals and found to be non-tuberculous, though the sections suggested sarcoma Another gland removed in the University Hospital was found to be the site of definite metastatic tumor growth

The x-ray findings in the mediastinum of tumor, the evidences of metastases in the glands of the neck, and Dr Spencer's histological studies make it fairly clear that the site of the primary tumor is the thymus and that the histological character of the tumor is of the reticulum-cell type In using the term "reticulum" Dr Spencer had in mind the reticular histiocytes and

the perivascular mesenchymal cells rather than the reticular epithelium

Whether this tumor should be regarded as sarcoma or as carcinoma is a question that merits discussion Much help in classification in the great group of lymphoid tumors may ultimately result from more general patronage of the "Lymphoid Tumor Registry" of the Army Medical Museum in Washington

Dr Spencer leans to the view that the neoplasm in our patient should be designated a "lymphosarcoma" and in this assumption he would be in accord, I believe, with one of our best American authorities on neoplasms, Dr James Ewing of New York The character of the cells of the tumor and the vascularity of the growth are the points upon which this diagnosis of lymphosarcoma is based Warthin of Ann Arbor would probably have placed the tumor in the group that he designated "aleukemic lymphoblastomas," a group that contains round-cell sarcoma, lymphosarcoma, lymphoma, and lymphadenoma, and he inclined to the view that many tumors reported as originating in the thymus have probably been primary in the mediastinal lymph nodes

On the other hand, most will agree that both the cortical and the medullary cells in the thymus, including some of the reticulum cells, are originally of epithelial origin Moreover, the fact that metastasis is through the lymph channels to the lymph glands rather than through the blood is further evidence in favor of carcinoma rather than of sarcoma There are, therefore, many who would place this tumor in the carcinoma-

tous group. The French writers lean to carcinoma, the German authors to sarcoma when they describe thymic tumors of this sort. Perhaps we will do best to compromise, as Schridde does, and simply speak of a "malignant thymoma," not committing ourselves definitely as to whether the neoplasm is of mesoblastic or of epithelial origin. The marked polymorphism of the cells, emphasized by Ambrosini, is one of the chief characteristics of these thymic tumors and is very obvious in the microphotographs of the sections of the tumor of the patient before you (Figures 3 and 4).

The Anemia This anemia is clearly of the secondary rather than of the primary type and it is probably related to the tumor growth itself and the

toxins produced by the neoplasm. There is nothing in the blood suggestive of Hodgkin's disease, of leukemia, or of other blood dyscrasias.

The Undernutrition This man is fifteen pounds under calculated ideal weight and he reports that, during the past three months, he has lost a good deal of weight. He states, however, that he has never been overweight and that is not surprising since he is of asthenic habitus.

The Weakness This patient has complained much of his physical weakness and muscular fatigability. His eyelids do not droop, however, and his jaw muscles do not tire on chewing beefsteak. We must keep a close watch upon the muscular functions since myasthenic states, indistinguishable from myasthenia gravis pseudoparalytica,

FIG. 3. Section of excised lymph gland as seen under the low power of the micro-

have occasionally developed in patients exhibiting tumors of the thymus. In one of these reported by Mandelbaum and Celler (1908), the thymus tumor was described as a "perilymphatic lymphangio-endothelioma", in other instances, the tumor was described as lymphosarcoma (Hun)

The Dental Caries Though this patient has marked dental caries and some gingivitis, it is not probable that the trouble with the teeth and gums stands in any relation to the other clinical findings, except possibly to the secondary anemia to which it could have been a contributing factor

DIFFERENTIAL DIAGNOSIS

We have had a clear demonstration of the fact that enlargement of the lymph glands in the neck may, for a

time, puzzle the diagnostician. Thus, this patient was under observation during several visits at the hospital dispensary and was finally sent to the *City Hospitals* because he was believed by some to be suffering from tuberculosis of the lymph glands and of the left upper lobe, and by one of the examiners to be suffering from mediastinal tumor. Biopsy has finally proven that without doubt we have to deal with metastatic neoplasm of the cervical lymph glands and this fact (together with the x-ray findings and the general clinical study) points to the thymus gland as the probable primary site of the neoplasm.

Any space-occupying mass within the mediastinum may give rise to a variety of clinical phenomena, for we must not forget that increased pres-

FIG 4 Section of the excised lymph gland as seen under high power magnification

sure within the mediastinum can affect any one or several of a group of very important structures, including the large blood vessels, the heart, the trachea, the esophagus, the thoracic duct, the thymus gland, the lymph glands at the root of the lungs, and several very important nerves including the vagus and its branch, the recurrent laryngeal, the phrenic, and the sympathetic trunk. Symptoms and signs of space-occupying masses within the mediastinum are usually due to compression of one or another of these structures. As a rule, it is the large veins that are first compressed, especially the superior vena cava, and, accordingly, dilatation of the veins of the chest and of the neck is an early symptom in most cases. In this patient, it is surprising that there has been no greater compression of the veins than has occurred, though that there is already some collateral circulation is obvious.

Most space-occupying masses within the mediastinum are true tumors but other processes may simulate tumors.

Of the *primary tumors of the mediastinum*, thymus tumors, tumors originating in the lymph glands, thyroid tumors, and dermoid cysts, are the most common.

Of the *secondary tumors of the mediastinum*, it should be remembered that metastases into the lymph glands of the mediastinum can give rise to space-occupying masses within the chest; for example, we may find them in association with carcinoma of the stomach, of the lung, or of the breast. Carcinoma of the esophagus or of a bronchus can also through metastases give rise to such masses.

Inflammatory masses in the mediastinum may be due to tuberculous abscess, especially when secondary to caries of the cervical spine.

Aneurysm of the aorta or of a subclavian artery can also give rise to a space-occupying mass in the mediastinum.

It is an interesting fact that the majority of patients with true mediastinal neoplasms are in early or middle life, rather than in later life, though they may occur at either period.

Among the *compression phenomena* met with, when there is a space-occupying mass in the mediastinum, certain *subjective symptoms* are common —

- 1 An obstinate, dry cough, often metallic in type, and sometimes occurring in paroxysms.
- 2 Hoarseness and bitonal voice, due to pressure upon the left recurrent laryngeal nerve and the effect of this upon the left vocal cord.
- 3 Dysphagia, due to pressure on the esophagus.
- 4 Pains, due to pressure upon the intercostal nerves, pains that radiate into the neck and the walls of the thorax and, sometimes, into the arms.

Though these subjective symptoms are usually more or less prominent, there are also variable *objective findings*, which may include

- 1 Swelling of the superficial veins, limited to the upper half of the body and often more marked on one side than on the other.
- 2 Swelling of the whole head and neck due to edema (so-called "Stokes' collar"), not present in this patient.

- 3 More or less marked cyanosis
- 4 Changes in the lungs, due to infiltration of the tumor or to pressure upon the lung or a bronchus with production of atelectasis
- 5 Chylous hydrothorax, due to pressure upon the thoracic duct (not present in this patient)
- 6 Characteristic findings on x-ray examinations of the thorax
- 7 Evidences of metastases in regional lymph glands

Even before the biopsy of the cervical lymph gland, it was possible to rule out many of the affections that might otherwise have had to be considered. Thus, *sphilis* was ruled out by the negative serology, *tuberculosis* was made improbable by the absence of tubercle bacilli in the sputum, *leukemia* was ruled out by the negative blood picture, *Hodgkin's disease*, of course, had to be thought of and particularly, because in the blood there was a rather high count of the large mononuclears and transitionals, but there was no eosinophilia, the patient had no pruritus, and the lymph gland enlargement was restricted to the left neck, and primary *tumors of the nasopharynx* were eliminated by careful inspection of the nose and throat.

The great value of the x-ray examination of the thorax and of the biptic examination of the lymph glands of the neck are well-illustrated in this patient. Thus, the x-ray examination revealed the space-occupying mass and its site in the upper anterior mediastinum, pointing to probable origin in the thymus gland. The biopsy of the lymph gland proved that we were dealing with a neoplastic process and that the histological character of the neo-

plasm was very suggestive of a thymic origin. *I cannot emphasize too strongly the desirability, in doubtful cases, of resorting to biopsy of a lymph gland for differential diagnostic purposes.* The procedure is a very simple one and involves practically no risk to the patient. The results, for diagnosis, are, in many cases, positively decisive.

DIAGNOSTIC CONCLUSIONS

From what I have said, we are justified, I believe, in making the following multi-dimensional diagnosis:

- 1 Malignant thymoma of reticulum cell type, causing pressure on the left lung, the left phrenic nerve, and the left recurrent laryngeal nerve, dislocating the trachea and the esophagus and giving rise to metastases to the lymph glands of the left side of the neck
- 2 Undernutrition, 15½ pounds
- 3 Secondary anemia (red blood cells, 3,970,000, hemoglobin, 55 per cent, with moderate leucocytosis, 11,800-15,280)
- 4 Febrile reaction, temperature 99.4°-101.6°, perhaps dependent upon the neoplasm itself, perhaps due to acute pharyngitis or to bronchitis of streptococcic origin
- 5 Slight hypertrophic osteoarthritis of the thoraco-lumbar spine
- 6 Dental caries and gingivitis
- 7 Sebaceous cyst in the right neck

PROGNOSIS

As the patient has been sent back to the ward, we may, in his absence, discuss the prognosis.

Though temporary improvement can be brought about by therapy, the pros-

pect in a case of this sort, judging from past clinical experience, is that exitus will occur within twenty-one months of the time when the first symptoms appeared, or earlier

TREATMENT OF THE PATIENT

In my opinion, there is no indication for surgical intervention in this patient. Attempts to remove the intrathoracic tumor are unjustifiable. The risk from the operation itself would be very great, in the first place, and, in the second place, there is no probability that such surgical intervention would prolong life. Nor is there any advantage to be derived from removal of the lymph glands of the neck, except for diagnostic purposes.

The best therapeutic methods of intervention at our disposal are deep roentgenotherapy and radium therapy. It is possible that we may be able to reduce the size of the mass within the thorax and also the size of the enlarged lymph glands of the neck by such treatment. Of course, everything should be done, in addition, to build up the general health and strength of the patient by diet and by suitable hygiene. Unhappily, we must recognize that any favorable results of therapy will be of but temporary duration. Later on, it will be the duty of his medical attendants to ensure a gentle and easy death by the now well-known methods of inducing euthanasia in the victims of hopeless neoplastic disease.

The Management of Severe and of Atypical Hyperthyroidism*

By FRANK H. LAHEY, M.D., *Boston, Mass.*

WE wish to call attention to two thyroid states concerning which very little appears in the literature, and both of which possess very serious possibilities of fatalities unless properly appreciated and properly managed. The first is the patient with very severe hyperthyroidism bordering upon the so-called thyroid crisis, and the second is the state which we have termed apathetic thyroidism.

SEVERE HYPERTHYROIDISM

Patients with exophthalmic goitre apparently have the faculty of not infrequently leading their medical advisors into a false sense of security. This is perhaps due to the fact that patients with this disease are notably optimistic. Clinically this feature of optimism is very striking in hyperthyroidism. We have often said that so-called nervous states of thyroid origin differ from those of psychic or neurotic origin in that the patient with hyperthyroidism insists that he can do things in the way of physical effort, but actually cannot, while the latter one says he cannot do things, but actually can. The fact that patients even with quite

severe thyroidism are able to be up and about and to maintain at least in some measure their activity, tends also to lead one to the feeling that there is no real hurry about them, and that active measures may be put off from week to week, with the possibility of the appearance of a remission, which may, of course, be prolonged into a permanent one and complete relief from the disease.

Based upon an experience now with nine thousand three hundred thyroid operations, we have had it impressed upon us that patients with severe hyperthyroidism are always upon the verge of a thyroid crisis and require the addition of only seemingly slight factors to so intensify their hyperthyroidism that they progress into a real thyroid crisis with its extreme ceaseless agitation, delirium, vomiting, diarrhea and uncountable tachycardia.

In patients with advanced grades of hyperthyroidism we have seen toxicity intensified to a crisis by the occurrence of a superimposed infection such as an ulcerated tooth and its removal. Frequently it has followed the occurrence of follicular tonsillitis, acute appendicitis and acute influenza infection. We have seen an acute thyroid crisis appear following a simple perineorrhaphy with a general anesthetic,

*Scheduled for presentation at the Baltimore Meeting of the American College of Physicians, March 26, 1931

an operation for gall stones, and we have had patients in whom serious thyroid reactions have followed simple tonsillectomy with a general anesthetic. We have likewise seen patients with severe hyperthyroidism progress into thyroid crises with no apparent inciting causes.

We have learned in dealing with such a large number of these cases that if these patients are permitted to progress into the stage of intense thyroid intoxication where they are delirious, vomiting, overactivated and with exaggerated heart rates, a very large percentage of them will die in spite of all measures to get them out of their critical state. Based upon our own experiences with these critical states, we wish to call attention to the fact that the time to instigate active measures against thyroid crises is before they have actually occurred, and that if active measures are instituted at this stage, a majority of the patients will be kept out of the crises and can be gotten into such improved states that active measures such as surgery can be undertaken with relative safety and the course of the disease quite definitely checked.

One should have in mind that every patient with intense hyperthyroidism may at any time pass into a thyroid crisis, and attention should be directed toward detecting the earliest possible indications of an impending crisis, such as sudden and persisting increases in pulse elevation, definite increases in activation, particularly when associated with changes in the mental state such as irrationality. Perhaps the most certain forerunner of thyroid crisis is vomiting, as, if it persists with its de-

hydration and emotional upset, a thyroid crisis, if not already present, is quite likely to occur. Diarrhea is tolerated much better than is vomiting, but is not to be neglected as a possible warning of an impending thyroid crisis.

It is at the time that these early premonitory signs occur that active measures against the intensifying hyperthyroidism must be undertaken if we wish to save the lives of these seriously threatened patients. If these patients have not been receiving iodine, it should be given in the form of Lugol's solution by mouth, ten drops three to four times a day, by rectum if not tolerated by mouth, and if it is not possible to administer it by mouth or rectum, we have found that fifty minims can be put in 750 cc of salt solution and administered by hypodermoclysis.

Patients with an impending thyroid crisis are usually in a state of marked overactivation which must be controlled if their organism is to be protected against their own hypercombustion. This can best be done, in our experience, with morphia or sodium amytal. We have never used avertin, but if a serious case presents itself with wild activation and delirium, we are planning to employ it if morphia and sodium amytal do not quiet the individual. It is to be recalled that patients with intense hyperthyroidism tolerate good-sized doses of morphia, and it must be given until its effect is obtained or respirations reach a dangerously low level.

Of measures to combat impending thyroid crises, salt solution and glucose are, in our experience, the most strik-

ingly valuable. Those patients either in crises or on the verge of thyroid crises should receive a minimum of 3000 c.c. of salt solution with 150 gms of glucose every twenty-four hours until their urgent symptoms have diminished as evidenced by a drop in pulse rate, diminution in excitement, return of mental clearness and a disappearance of vomiting and diarrhea.

Just how glucose and salt solution protect these patients against the rapidly destructive effects of intense thyroidism, we cannot say. Whether it protects them by increasing the glycogen reserve in the liver, or whether it restores water balance and protects the organism against hypercombustion by providing a material which is readily burned, we do not know. We do know that the administration of salt solution and glucose in reasonably large doses has been the salvation of many patients in severe post-operative thyroid reactions and in patients already in severe thyroid crises when coming to the Clinic, and that its employment as suggested above on the slightest warning of an impending crisis has prevented many patients from progressing into a serious thyroid crisis, and so undoubtedly saved their lives.

We feel sure from our experiences with these cases that it is a mistake not to have them operated upon as soon as one reasonably can after recovery from the crisis or threatened crisis, as they are still intensely toxic and capable of again being precipitated by another infection into another crisis. We believe that any patients who have hyperthyroidism of such a severe degree that they are in danger of a crisis, should be definitely freed from that

toxicity as quickly and as completely as possible by such an active measure as subtotal thyroidectomy.

APATHETIC THYROIDISM

We have from time to time written about what we have called apathetic thyroidism, and I am anxious to present this subject to several different groups of medical men because I feel sure that its diagnosis is often overlooked and certainly its seriousness often underestimated.

The signs of so-called apathetic hyperthyroidism are quite contradictory to those of typical hyperthyroidism or exophthalmic goitre which is of the type which we have called activated in contradistinction to this inactivated or apathetic type.

Activated or typical hyperthyroidism tends to occur in the majority of cases, in patients up to forty or fifty years of age. Apathetic hyperthyroidism tends to occur in patients above forty to fifty years of age. Activated hyperthyroidism is characterized by quite definite eye signs, not always exophthalmos but usually stare. The eyes in apathetic hyperthyroidism are usually not characterized by exophthalmos, are in repose, and not staring. The thyroid of activated hyperthyroidism is particularly apt to be larger than normal and of a definite firm hyperplastic character. The thyroid in apathetic hyperthyroidism tends to be smaller than that which is found in activated hyperthyroidism, although in these conditions the size of the gland may be reversed. Pulse rate in activated hyperthyroidism tends to be high and of a striking character, snapping and full; while the pulse rate of apathetic hyperthyroid-

ism tends to be relatively low, one hundred and twenty or under, and not particularly striking and snapping in character. The apex impulse in activated hyperthyroidism tends to be impressively tumultuous and thrusting so that it is diffused over the entire precordia. The apex beat of apathetic hyperthyroidism is not at all of this character. It is not striking. It is not forceful and is not diffused over the precordia. Patients with activated hyperthyroidism tend very distinctly to have a youthful appearance, even those patients of advanced years who show the activation type of hyperthyroidism are made to look much younger than they really are. This is due to the fact that patients with activated hyperthyroidism are energetic, quick in motion, their skin is warm, moist and flushed and of the soft velvety texture which so frequently is associated with youth, while the skin of patients with apathetic hyperthyroidism is quite the opposite and causes their general appearance to be one of greater age than they actually are. Thus, the skin in patients with apathetic hyperthyroidism is cool, dry, wrinkled and pigmented, and in addition the patient is tired, sluggish, and even apathetic. All these features tend to give the patient with apathetic hyperthyroidism an appearance of advanced years as compared with the converse youthfulness of patients with activated hyperthyroidism. Patients with activated, typical exophthalmic goitre usually have had the disease over a shorter period of time than those with apathetic hyperthyroidism. Patients with apathetic hyperthyroidism tend to have the disease in a rela-

tively non-activated form over several months or several years. The weight loss in the activated typical hyperthyroidism is fluctuating, there being periods when there is considerable weight loss and periods in which it is regained. The weight loss in apathetic hyperthyroidism tends to be marked. It occurs quite gradually but progressively over a long period of time, so that it is not an impressive feature in the patient's mind. The basal metabolism of typical activated hyperthyroidism tends to be high, from plus forty, fifty and sixty upwards, to often over plus one hundred. The basal metabolism of apathetic hyperthyroidism tends to be relatively low, from plus forty downward, even as low as plus twenty.

We have had the opportunity several times to observe the course of patients dying from the two different types of hyperthyroidism and their behavior even in this unfortunate situation is entirely different. Patients with activated hyperthyroidism die in a marked state of agitation. They are delirious. They thrash about and are difficult to control. Their pulse rates rise to uncountable heights. Patients with apathetic hyperthyroidism die in quite an opposite manner. If operated upon, they go back to their beds, often with pulse rates of one hundred and twenty or under, in no way agitated, and sink gradually and apathetically into stupor, coma and death.

The course of the two conditions under the stress of an operative procedure is also quite different. Patients with activated hyperthyroidism, while being operated, frequently show marked elevation in pulse rate and marked general activity, while those

with apathetic hyperthyroidism, while being operated upon, frequently show pulse rates ranging between one hundred and one hundred and twenty, not of the toxic character and, in addition, show no signs of activation

These patients with apathetic hyperthyroidism are those in whom unexpected fatalities frequently arise. They are the patients in whom, because of their low basal rate, their lack of pre-operative activation and agitation, their apparent repose, and their apparently safe course while on the operating table or under any stress too much surgery is done at one time. They are the patients in whom we have had practically all of our unexpected fatalities in the surgery of hyperthyroidism. Patients with activated hyperthyroidism are so impressive as to the intensity of their intoxication that the fact that a dangerous condition exists is always uppermost in one's mind. This is distinctly not true of the patients with apathetic hyperthyroidism and one is not infrequently led into a false sense of security, because as a matter of actual experience, it is the patient with apathetic thyroidism,—that is, the patient with marked weight loss, with hyperthyroidism of long standing, the non-activated patient past fifty years,—in whom the addition of any extra burden, operative or non-operative, will result in an unexpected fatality.

We are of the opinion that because of the lack of striking signs and symptoms many of these patients, particularly with small thyroids, go a number of months and years undiagnosed, and we are so distinctly of the opinion that they are particularly bad risks that we have assumed the position that

any patient showing apathetic hyperthyroidism, no matter how good he may appear as a risk, must be operated upon in two stages,—a right subtotal hemithyroidectomy being done first, the patient sent home for six weeks, during which time there is usually marked improvement, to then return to the hospital for a second stage removal of the left lobe.

We have been able to maintain a mortality in the entire series of 9300 thyroid operations of not over one per cent, and within the last few years we have been able to reduce the mortality in toxic goitre to a range of from 0.27 per cent to 0.6 per cent. This includes thyrocardiacs, patients who have been in thyroid crises, and also patients with apathetic hyperthyroidism. It includes the entire group of thyroids coming to the Clinic without rejection. We believe, however, that this mortality rate can be maintained only by an appreciation of the fact that the most serious risks are not in the patients who appear to be in the most serious state, but in those patients of older years, with slow and progressive weight loss, who are apparently good risks, but actually a group in which we have the highest mortality rate.

CONCLUSIONS

A very large percentage of patients who are permitted to get into the advanced state of thyroid crisis will die. Their salvation is the early detection of an impending thyroid crisis or undue intensification of their hyperthyroidism and its emergency treatment with iodine, morphine, amytal, avertin.

salt solution and glucose. By the early application of these measures, patients may be kept out of thyroid crises, prepared and operated by subtotal thyroidectomy within three weeks and definitely relieved of their thyroidism.

Apathetic hyperthyroidism is a state characterized by signs and symptoms quite contrary to those of typical activated hyperthyroidism. It is misleading, not only as to its existence, but it is also misleading as to its seriousness, and possesses graver dangers of a fatality under stress or operative procedure than does the typical activated hyperthyroidism. An appreciation of

its atypical signs and symptoms will result in its early diagnosis and an appreciation of its certain unobtrusive seriousness should make one realize the possibilities of a fatality when the patient is submitted to any considerable extra burden, particularly such as subtotal thyroidectomy in one stage. It should make one undertake surgical procedures in all patients of this type, no matter how good they appear as risks, in two stages. Its earlier recognition and submission to surgery will result in a considerable lowering of its operative and non-operative mortality rate.

Fallacies and Dangers in the Treatment of Exophthalmic Goiter by Iodine*†

By WILLARD OWEN THOMPSON, M D, F A C P, and
PHEBE K THOMPSON, M D, *Chicago, Ill*

UNTIL about ten years ago, the treatment of exophthalmic goiter by iodine was considered a dangerous procedure, although it was not claimed that its immediate effects were always harmful. The attitude then prevalent is fairly well expressed in the statement of T Kocher¹ "Es ist ein zweischneidigen Schwert und der Schaden überwiegt" (it is a two-edged sword and harm predominates). Following the demonstration of the clinical improvement and the reduction in basal metabolism during its administration to patients with toxic goiter², the pendulum swung almost completely to the other extreme. The consequence has been that most beneficial results that occur during its administration are attributed to iodine and most unfortunate results to the natural course of the disease. This is perhaps inevitable and it will probably be several years before the effects of iodine are precisely defined from an unprejudiced point of view. In the meantime, certain considerations appear pertinent.

*Received for publication, September 3, 1931.

†From the Department of Medicine, Rush Medical College and the Presbyterian Hospital, Chicago, Ill.

IODINE AND THE MORTALITY RATE

It is generally agreed that iodine, by reducing the intensity of the disease, has diminished the risk of operation. However, it would seem that the reduction in mortality caused by iodine is often overestimated. Before the days of iodine the mortality had steadily diminished as experience in treating the condition increased. From 1894 to 1907, according to the table in Crotti's³ book, it varied from 28.5 to 30.0 per cent with a mortality over 10 per cent in ten of twenty-three reports. From 1908 to 1917 it varied from 0 to 13.1 per cent (excluding one report in which data were collected from the literature without dates being given) and it was over 5 per cent in only seven of twenty-eight reports. The Mayos⁴ had 4 deaths in their first 16 operations, 3 in the next 30 and 3 in the next 150. From 1907 to 1920 their mortality varied from 2 to 5 per cent, with the general trend downwards and it was, for the most part, under 3 per cent after 1912. For the years 1921, 1922, 1924, 1925, 1926, 1927 and 1928 it was 3.39, 1.74, 0.8, 1.1, 0.83, 0.7, and 1 per cent respectively, according to Pemberton⁵. Iodine

was introduced at the Mayo Clinic in March, 1922

Crile⁶ in 1920 published a chart showing his mortality from June 28, 1906, to October 1, 1919. At first he used ether alone for anesthesia and his death rate was 16 per cent in the first 50 operations. Then with anociation, nitrous oxid-oxygen and local anesthesia with anesthetization of patients in their rooms, the mortality promptly dropped to 4 per cent. It then fluctuated between 2 and 5 per cent for several years until the adoption of his "new technique," which still further reduced the element of fear. With this the rate in exophthalmic goiter was 11 per cent, and in all thyroidectomies it was 0.6 per cent. In 1929 he⁷ reported a mortality of 0.6 per cent in his last 1000 thyroidectomies.

Lahey, in 1916⁸, reported the mortality as varying from 2 to 7 per cent in his operations for exophthalmic goiter. In 1922⁹ this had been reduced to about 1.17 per cent, a rate which was little affected by iodine because this element although introduced into his clinic in 1922, was used only in occasional cases at first. For the five-year period from 1925 to 1929, the mortality as given by Clute¹⁰ was approximately 0.2, 1.8, 1.6, 0.7, and 0.1 per cent respectively.

Porter¹¹, in 1923, reported the results of thyroidectomy in 204 cases of exophthalmic goiter as follows:

1904-1908	No mortality
1909-1914	15 per cent
1914-1919	14 per cent
1919-1920	8 per cent
1920-Jan 1921	3 per cent

Crotti³ gives Kocher's mortality as follows:

Year	No Cases	Death Rate (per cent)
1902	59	6.5
1906	167	5.0
1910	376	4.0
1911	167	2.3
1912	130	1.5
1916	300	1.0

Richter¹², in 1929, reported a mortality of 0.2 per cent in 500 consecutive thyroidectomies, whereas his rate was 1.0 per cent before iodine. In 1920, Frazier¹³ was able to report a mortality for toxic goiter for the preceding five years of between 1 and 2 per cent. Riedl¹⁴ had a mortality of 40 per cent in his first 40 cases and 3.3 per cent in the following 30. Crotti's³ mortality was 8 per cent in his first 100 cases, 7 per cent in the next 122, 3.2 per cent in the next 100, and there were no deaths in the last 137 cases he reported in 1917.

It may thus be seen that in many good clinics before the days of iodine, the mortality from operations for toxic goiter was as low as 1 per cent, and that in the hands of leading surgeons it has dropped from about 1 to 4 per cent to about 0.25 to 0.7 per cent since the introduction of iodine. In spite of iodine, some good surgeons now have a higher mortality than others before the days of iodine. Thus von Eiselsberg¹⁶ reported a mortality of 6 per cent in 1930, and Dunhill¹⁷ of 2.7 per cent in 1930. In fact, Bevan¹⁸ is of the opinion that the average mortality for this country at present is between 3 and 5 per cent. In interpreting such data it must, of course, be borne in mind that a thyroid operation before the days of iodine was usually less extensive than now and that some patients who previously would have died

before operative interference was possible, are now operated upon

REST AND THE IODINE REACTION

In cases of toxic goiter, it is common practice to determine the basal metabolism the day after admission to the hospital and again one or two days before operation, and to attribute any reduction that may have occurred in the interval to iodine. Striking clinical improvement and reduction in basal metabolism often occur from rest alone, whether patients are completely confined to bed or whether they are allowed the usual privileges of ambulatory ward patients. Most of the immediate reduction from rest appears to occur in the first few days.¹⁹ In trying to determine the range of effective iodine dosage in exophthalmic goiter, we²⁰ observed the effect of the daily administration of roughly 0.75 mg., 1.5 mg., 3.0 mg., and 6 mg. of iodine. It so happened that in the case of the two smallest doses, the effect of rest was greater than the effect of the small doses of iodine and, in the case of the second largest dose, its effect was just as great. It would, therefore, have been impossible to compare the effects of these different doses of iodine without having secured a level of basal metabolism during rest. Similarly the amount of clinical improvement and the amount of reduction in basal metabolism caused by large doses of iodine in any part of the country can be accurately gauged only when the effect of rest alone on these two factors under the same conditions is determined.

REFRACTORINESS TO IODINE AND ITS MANAGEMENT

It is important to determine whether patients with exophthalmic goiter ever develop a tolerance to iodine. Many observers have reported that, during its prolonged administration, the basal metabolism, after showing an initial reduction, may rise to a higher level than it was before iodine was started, and the patient becomes worse. In spite of this, it has been claimed that the peculiar nervous manifestations of the disease are always under control at all stages in this response and that the variations in metabolism are the result of spontaneous variations in the disease and independent of the iodine. Thus, according to this theory, iodine should never be omitted because its effect never wears off while it is being given in excess.

Our experience has not led us to a similar conclusion. In patients whom we have observed when the metabolism was rising in spite of the administration of iodine, all of the manifestations of the disease including the peculiar nervous ones, were becoming more marked. Under such circumstances, we have seen exophthalmos not only increase but appear for the first time.²¹ The end result of such a reaction may be the development of refractoriness to iodine, examples of which have been reported elsewhere.²¹ When patients are refractory the disease usually flourishes in a severe form. We²¹ have elsewhere reported a patient who had a thyroidectomy when his metabolism was rising rapidly during the administration of iodine and who died of a typical crisis sixty hours after opera-

tion There had been a marked temporary improvement which had lasted only a short time before the metabolism began to rise Before the days of iodine, many observers (e. g., Means²², Mayo²³, Crotti³, Plummer²⁴, Else and Irvine²⁵) had pointed out that it was unsafe to operate during a period of rising metabolism This would still appear to be a contraindication to operation, even if iodine is being administered

That patients may become refractory to iodine during its prolonged administration is supported by the observation of several workers Jackson²⁶ has noted that "the greatest risks (i. e., operative) occur when patients have been given iodine for many months until they develop a tolerance to it", in such patients "the same reaction" after operation "is expected as before iodine was used" According to Graham²⁷, "clinical experience has demonstrated the utter futility of further iodine therapy in the already overiodinized patient" He considers such patients poor operative risks. Frazier and Mosser²⁸ have gone so far as to say that indiscriminate and prolonged administration of iodine "has to a large extent deprived the surgeon of this safeguard, and we have again been forced to operate in an increased number of cases by the fractional method" Graham²⁹, Campbell³⁰, and Goetsch³¹ are of the impression that operation in a patient who shows a high metabolism and is very sick after the prolonged administration of iodine may cause the death of the individual.

The possibility must, therefore, be considered that in certain cases of exophthalmic goiter the administration of

iodine may stimulate some reaction to it which tends to counteract its beneficial effect In support of this is the fact that a dose of iodine which in itself is too small to cause any reduction in basal metabolism, may interfere with the effect of much larger doses administered immediately afterward³².

The percentage of patients that will develop refractoriness to iodine during its prolonged administration is unknown Refractoriness appears to us to occur primarily in moderately severe and severe cases rather than in mild cases³³ We have reported mild cases in which the metabolism could be held depressed at a constant level for years by continuous administration of iodine^{33,34} The importance of operating as soon as the maximum reduction in basal metabolism occurs seems to us to have been exaggerated It appears safe to postpone operation at least from one to two weeks beyond the time of maximum reduction in all but the more severe cases In other words, it would seem that the more severe the case the more rapidly refractoriness develops

Contrary to the general belief, it has been our experience that after a short period of freedom from iodine (usually four weeks) patients will lose their refractoriness to it and again show a well marked response Both Graham²⁷ and Coller³⁵ have observed a similar phenomenon Thus, in all patients who have developed marked refractoriness to iodine, it seems to us unwise to resort to any operative interference until iodine has been omitted long enough for the refractoriness to disappear^{21, 36}

It should be emphasized that iodine

has not completely abolished postoperative reactions. It has merely reduced their number and intensity. We still occasionally see severe reactions in patients who show a well marked improvement during the preoperative administration of iodine. One of our patients recently died from a typical crisis 60 hours after operation, in spite of the fact that her basal metabolism had dropped from plus 100 to plus 30 per cent and her pulse from 120 to 60 with rest and iodine before operation. Most clinics still report a few deaths each year from postoperative crises in spite of iodine administration, although, of course, the number has been markedly reduced (e g., at the Mayo Clinic from 1 per cent to 0.14 per cent³⁷).

Lahey³⁸ has remarked "It is distinctly possible that the apparent improvement following the use of Lugol's may be so great that one is led to do a complete operation only to have the patient die in intense thyroidism." Clute³⁰ of the same Clinic has said "With multiple stage operations the mortality of primary hyperthyroidism was reduced to less than 1 per cent in this clinic and we hesitated to adopt the more radical procedure of thyroidectomy in one stage, which was popular after iodine preparation. In 1925, however, we became more radical and, to a large extent, we permitted iodine to replace pole ligations. The number of stage operations fell from 65 per cent, the figure before iodine was used, to 21 per cent. The mortality rose at once to 2.06 per cent." Dunhill¹⁷ has very aptly remarked that iodine "has helped so greatly that the literature would lead us to believe that the opera-

tion is now quite safe, that the necessity for ligations of arteries has passed and that generally the complete procedure may be employed in one stage. To some extent this is true but it is not completely true." It is his impression that unless graded operations are carried out in patients who do not respond well to iodine "the death rate will be unduly high."

Observation of a large number of patients at all stages in their response to iodine has convinced us that iodine does not cause the complete disappearance of the emotional manifestations of the disease, it merely reduces their intensity, which varies roughly with the basal metabolism. It sometimes may exert no apparent influence. Lahey³⁹ and Clute⁴⁰ have reported patients who died in crisis before operation could be considered, in spite of "the most active measures including iodine in large doses." Increasing experience with iodine thus seems to justify the conclusion that the control it exercises over the disease is relative and not absolute, and that after it has been administered for a long time, its beneficial effects may disappear entirely. In other words, there is more to the treatment of exophthalmic goiter than the administration of iodine and the performance of a subtotal thyroidectomy. The lessons learned before the days of iodine cannot be ignored now if the mortality is to be kept at a low level. Among factors that seem to be of importance in achieving this end may be mentioned

- 1 The skill of the surgeon
- 2 Proper selection of the time of operation—in particular avoiding operative interference at times when the

patient has developed or is developing refractoriness to iodine

3 The type of operation.

4 A diet sufficiently high in calories to make the patient gain weight before operation. This should also be high in protein (roughly 1.5 to 2 grams per kilogram of body weight), because of the rapid breakdown of protein in this disease

5 Abolition of fear, worry and other psychic traumata

6 Attention to fluids and calories in the immediate postoperative period

7 Proper selection of an anesthetic

About the third point there is some dispute. Before the days of iodine, most surgeons were of the impression that stage operations had been a factor in reducing the mortality. Several observers, notably those at the Lahey Clinic¹⁰, still insist that they should be done in all doubtful cases and consider them important in their low mortality. Richter¹², on the other hand, has always maintained that his low mortality, even before iodine, has in part been the result of rarely doing a thyroidectomy in more than one stage. Richter's mortality is about the same as Lahey's. We are somewhat at a loss to reconcile these divergent points of view.

We wish to make it clear that this is not an attempt to minimize the value of iodine in the treatment of exophthalmic goiter. Indeed, we regard the treatment of this disease with iodine as one of the most important advances in recent times. We do feel, however, that accurate evaluation of the effects of iodine will save us from certain pit-

falls of the past and will in no way detract from its importance

SUMMARY

Since the introduction of iodine the mortality from thyroidectomy for exophthalmic goiter in the leading clinics, has been lowered from about 1 to 4 per cent, to about 0.25 to 0.7 per cent. This reduction is, we believe, less than is generally appreciated.

The actual clinical improvement and reduction in basal metabolism caused by iodine is also somewhat less than is generally appreciated, owing to the fact that the influence of rest is usually not controlled.

In very severe cases of the disease operation should be performed as soon as the metabolism reaches a level during the administration of iodine, because the beneficial effects in such cases may be of short duration.

In cases in which the basal metabolism is high after the prolonged administration of iodine and those in which the basal metabolism is rising rapidly during the administration of iodine, no operative procedures should be undertaken until iodine has been omitted long enough for the refractoriness to it to disappear (usually about four weeks), and then readministered.

In the routine preoperative treatment of exophthalmic goiter it is desirable to give suddenly an adequate excess of iodine and not to precede this with small doses.

A few patients still die from typical postoperative thyroid crises in spite of the administration of large doses of iodine. These reactions sometimes occur in patients who have shown satisfactory responses to iodine before operation.

There is more to the treatment of exophthalmic goiter than the administration of iodine and the performance of a subtotal thyroidectomy. The skill of the surgeon, selection of the time and type of operation, proper attention

to calories, protein, and fluid in the preoperative and postoperative periods, abolition of fear and worry, and the type of anesthesia, all seem to be factors of importance in keeping the mortality low.

Subacute Bacterial Endocarditis Following the Extraction of Teeth: Report of a Case*†

By MITCHELL BERNSTEIN, M D , F A.C P , *Philadelphia, Pa*

SUBACUTE bacterial endocarditis may be overlooked, or it may be masked as another disease, as in the case to be reported, for some weeks, before the true nature of the disease is recognized. Moreover, the importance of being mindful of this disease in every case of illness associated with continued fever, cannot be over emphasized.

Jules B, aged 25, a law student, complained on January 15, 1931, of having a slight fever every afternoon, night sweats of moderate severity and weakness.

His family history was essentially negative. During childhood he had measles, mumps, diphtheria and chorea. In addition, he had rheumatic fever when he was eight years of age. Subsequent to this he was told that he had "some valvular lesion" although it apparently caused him no discomfort or incapacity.

The present illness dated from December 20, 1930, when two non-vital abscessed molar teeth were extracted under local anesthesia. Following the extraction of these teeth, the patient bled profusely. Packing of the teeth sockets was necessary and despite this procedure the bleeding continued for three days. On the fifth day following the extraction of the teeth, the patient developed fever but had no other definite symptoms. The fever continued and on January 5, 1931,

the patient consulted a physician who advised return for dental examination. The teeth sockets were curetted and free drainage instituted. Despite this procedure the fever continued, ranging from 99°F to 100°F. Meanwhile the patient was up and about, attending to his daily routine. He consulted several physicians who told him that he had a mild attack of grippe.

On January 15, 1931, 26 days after the extraction of the teeth the patient first came under my observation. His temperature was 102°F. He was rather pale. The site of the dental extraction showed no signs of infection. The tonsils were absent. There was a pulsation at the root of the neck. Physical examination of the lungs showed no abnormalities.

The heart was enlarged to the left, the apex being in the fifth left interspace, 14 cm to the left of the midsternal line. The right border of the heart was at its normal position. No thrill was palpable. On auscultation at the apex of the heart, a soft systolic murmur was heard and this was transmitted to the left axilla. In addition, at the aortic area, an aortic diastolic murmur was heard and this was transmitted down the left side of the sternum. The heart rate was 100 to 110 per minute and the blood pressure was 120 systolic, and 60 diastolic. A Corrigan's pulse was present.

The examination of the abdomen was essentially negative except for a slight enlargement of the spleen on percussion. Examination of the extremities was negative. The urine proved to be normal. The blood count showed 13,800 leucocytes of which 86 per cent were polymorphonuclears.

On January 16 the blood count showed 13,000 leucocytes of which 90 per cent were

*From the service of Dr Thomas McCrae, Jefferson Medical College Hospital, Philadelphia, Pa

2

Chart 1B The temperature and pulse ranges throughout the course of the disease

polymorphonuclears, while on January 17 the blood count showed 12,000 leucocytes and 85 per cent polymorphonuclears

In view of the history of previous rheumatic fever together with clinical evidence of valvular disease, involving the aortic and mitral valves, the diagnosis of subacute bacterial endocarditis was made

A blood culture which was taken in the meantime, showed after 48 hours, a profuse growth of *streptococcus viridans*

On January 19, 1931, the patient was admitted to the service of Dr Thomas McCrae, at the Jefferson Medical College Hospital. The blood count showed 87 per cent hemoglobin, 4,410,000 red blood cells, 12,300 leucocytes, 86 per cent polymorphonuclears, 13 small mononuclears and 1 large mononuclear. A blood culture taken following the patient's admission to the hospital, showed a profuse growth of the *streptococcus viridans*. Subsequent cultures of the patient's blood taken at intervals, always showed the *streptococcus viridans*.

The fever continued, as did the night sweats. The physical signs remained practically unchanged until March 1, 1931. At that time there was tenderness over the spleen. The tips of the patient's fingers were tender and showed a few small embolic areas.

On March 16, 1931, the patient complained of blurred vision. Additional embolic areas were present in the finger tips on March 30. There was considerable precordial distress and palpitation.

On April 19, the patient complained of severe pain in the region of the spleen. This organ was tender and on percussion was found to be enlarged. The pain in the splenic area continued for three days. Pain over the spleen recurred on April 27 and a friction rub was detected over the splenic area. Meanwhile the fever was continuous, the temperature ranging from 97°F to 102°F and later reaching 104°F, as will be seen from the temperature chart (temperature chart reproduced). The anemia was slightly increased. Blood cultures continued to be positive for the *streptococcus viridans*. The patient had become quite emotional and very apprehensive.

On May 18, the physical signs of congest-

tion were detected in the left lung, at the base, posteriorly. In addition, the heart rate was 120 to 130 per minute. On auscultation the aortic diastolic murmur was very loud as was the mitral systolic murmur.

The following morning, May 19, at 2 P. M., the patient died.

The duration of the illness from the time of the onset of symptoms was about six months.

Post mortem examination was not permitted.

Additional Data. Daily examination of the urine failed to show red blood cells at any time during the course of the disease. The specific gravity varied from 1004 to 1022. There was from a faint trace to a trace of albumin, and at times none. Casts were found in the urine toward the termination of the disease. Blood cultures were taken on January 22, 27, February 4, 25, March 4, and April 8 and proved positive for *streptococcus viridans*.

Various blood counts done at intervals were as follows:

		Hg	RBC	WBC	Poly	SM	I M	Eosin
Jan 20	87%	4 410,000	12 300	86	12	2	2	
Jan 30	78%	4 100,000	12,000	70	24	4	2	
Feb 12	76%	3 050,000	13 000					
Feb 24	72%	4 030,000						
Mar 31	82%	4 200 000	14 000	65	25	8	2	
May 1	76%	3,900,000	19,000	72	24	2	2	
May 11	75%	4,020,000	15,600					

On February 11, 1931, the icterus index was eight units. The Van den Bergh test showed an indirectly weakly positive reaction. The blood Wassermann reaction was negative.

Various forms of treatment were used but all proved of no avail.

COMMENT

The occurrence of the infection within five days following the extraction of the teeth and subsequent packing of the sockets raises the question as to whether the infection was disseminated on account of the trauma at the time of the extraction of the teeth or at the time of packing or whether an infection was introduced at the time

CHART 1C The temperature and pulse ranges throughout the course of the disease

CHART 1D The temperature and pulse ranges throughout the course of the disease

of packing, by the use of materials and instruments which may not have been sterile. At any rate, both procedures should always require absolute sterility of all instruments used by the dental surgeon.

Furthermore, the question of the advisability of removing infected teeth from a patient with rheumatic heart disease, because of the danger of the

occurrence of subacute bacterial endocarditis, seems very pertinent. Although it is a known fact that scores of infected teeth are extracted daily, yet it would seem from the foregoing case report, that the procedure is not without danger. Just how this danger may be avoided by other than the usual precautions of sterility during extraction of teeth, remains a question.

The Management of Coronary Thrombosis and Its Complications*

By BLANTON P SEWARD, A B , M D , F A C P , *Roanoke, Va*

THE increasing frequency with which the diagnosis of coronary thrombosis with myocardial infarction is being made indicates that it is a relatively common disease. In the majority of cases it can be diagnosed at the bedside, but an important aid in its recognition is the electrocardiogram, since clinical and experimental investigations have shown that certain changes in the ventricular complex are associated with obstruction in a coronary artery. While these changes are a valuable aid in the diagnosis, especially of suspicious and atypical cases, they are not invariably diagnostic for they are found in electrocardiograms in other cardiac conditions. Electrocardiography has justifiably achieved a place of importance in the diagnosis of coronary thrombosis, and recent work¹ in the correlation of the electrocardiographic phenomena with the pathological changes found in the hearts of patients who have died of coronary thrombosis, indicates the possibility of localizing the region of the coronary system involved by the obstruction with the accuracy that obstructive lesions in the cerebral arteries are localized.

While our knowledge of the clinical features and of the pathological changes subsequent to the thrombosis of a coronary artery has been greatly extended, no fixed methods of treatment of this condition and its complications have been formulated. Methods of treatment found in the literature are no more than brief outlines omitting many details of importance. This is not surprising since it has been only in recent years that the first diagnosis of coronary thrombosis was made. In addition, the rapidity of the progress of the disease in many patients and the suddenness with which complications may arise, make it extremely difficult to evolve a system of treatment. However, bearing in mind the gross anatomical changes which occur in the heart following thrombosis and the pathological physiology accompanying these changes, further experience will aid in working out a more satisfactory plan of treatment. In the light of our present knowledge there are certain principles which may be followed in the proper management of this condition and its complications.

MANAGEMENT DURING THE ACUTE ATTACK

With the onset of the attack the outstanding symptom is pain which

From the Department of Medicine
- Gale Hospital, Roanoke, Va
Submitted for publication, June 1 1931

if possible, should be relieved. The pain may be severe from the first or it may begin as a mild discomfort and increase in intensity until it becomes agonizing. In either instance morphine in sufficient doses, one-fourth to one-half a grain, must be given as often as necessary to control the pain. Coronary thrombosis is one condition in which we are justified in giving large doses of morphine, since it not only gives relief from the pain, but aids in producing mental and physical rest. There is no contra-indication to its use, although when the pain is located in the epigastrium the physician should be reasonably sure before giving much of it that the pain is caused by the occlusion of a coronary artery and not by an acute lesion in the upper abdomen which may require surgical intervention. The continued use of morphine may be necessary for a few days, after which the milder sedatives, such as the bromides and occasional doses of codeine or morphine, will usually allay the pain and restlessness.

The hypnotics and anodyne preparations synthesized from barbituric acid, such as allonal, amytal and luminal, are frequently given to relieve mild pain and restlessness in many conditions, but we prefer not to use them in this disease on account of their depressing effect. The nitrites, so valuable in the treatment of angina pectoris, do not relieve the pain caused by the occlusion of a coronary artery. They are not only useless in this condition, but as a falling blood pressure accompanies thrombosis, these drugs may do harm by reducing the pressure still further.

Soon after the beginning of an at-

tack, a state of shock develops and it should be treated in much the same manner as in other conditions. The body should be kept warm by the application of warm blankets and hot water bottles, but stimulation should be avoided unless heart failure is threatening. In all cases the heart sounds soon become distant, the quality of the first sound indicates poor muscle tone; the regular rhythm may be interrupted by an occasional extrasystole; the systolic pressure may fall to 100 mm of mercury or lower, and an ashen color will be observed. Shock may be of mild degree, and the relief of pain and the application of heat may be all the measures required in the immediate treatment of many of these patients, who will often show improvement in a few days.

Other patients are more severely shocked, especially when the pain persists any length of time. In these the cardiac sounds are more feeble and arrhythmic, the pulse is small in volume or imperceptible, the respirations are irregular and shallow and cyanosis is more pronounced. When such signs prevail gentle stimulation with caffeine sodium benzoate is necessary, in addition to the application of heat and the administration of morphine. Three to five grains of caffeine may be administered intramuscularly every two hours for a few doses or regularly for a day or two according to the requirements of the patient. In small doses caffeine strengthens the heart beat, stimulates the vasomotor center causing vasoconstriction, and stimulates the respiratory center, causing an increase in alveolar ventilation. On the other hand, large doses of caffeine have been

shown experimentally to increase the tendency to cardiac failure by depressing the heart muscles, and also to paralyze the blood vessel walls² Large doses of this drug should not be given Caffeine has a definite place in the treatment of coronary thrombosis and its judicious use appears to carry some of the patients through the crisis If the condition of the patient requires stronger stimulation, eight to ten minims of epinephrine may be given, but in our experience when strong stimulants are required the patient is beyond hope of recovery

There is little that can be done for the nausea and vomiting which are so often present In many patients the nausea subsides in two or three days, while in others it may persist for a week or longer, making it difficult for them to take an adequate amount of nourishment, or of fluid to prevent dehydration When fluid and nourishment cannot be taken by mouth in sufficient amounts, they should be given daily by other routes It is better to avoid giving large amounts of fluid intravenously as the greatly increased volume in the circulation will increase the work of the heart and may still further embarrass its action On the other hand, small quantities of a concentrated solution of glucose may be given intravenously without endangering the heart To patients who have much nausea we give routinely 30 to 40 c c of 50 per cent solution of glucose intravenously once in twenty-four hours, supplemented by 500 to 1000 c c of normal saline with 5 per cent glucose by rectum until they are able to take a sufficient quantity of fluid and food by mouth An improvement

in the quality of the sounds as well as in the volume of the pulse is a common observation after glucose is given intravenously The administration of glucose is physiological in principle and a valuable supporting measure in the treatment of coronary thrombosis since it serves as a source of readily available energy, thus aiding the heart in maintaining its functional integrity The use of glucose should be continued until the patient can take a sufficient quantity of food and fluid by mouth When nausea is very annoying we do not attempt to give anything by mouth for twenty-four to twenty-eight hours except enough water to prevent excessive dryness of the mouth and throat While this does not cause the nausea to subside entirely, in some instances it increases the patient's comfort and enables him to take water and nourishment more easily when oral feeding is resumed

An increase in the blood urea is observed during the first week after coronary thrombosis This increase, due to stasis of the circulation and passive congestion of the kidneys, is usually not marked, although if the patient has chronic nephritis, it may rise to a high figure, as, for example, to 180 mg per 100 c c of blood in a patient seen recently Uremia may then seem imminent, but we have not seen it develop in such patients We do not attempt to reduce the urea since the patient's weakness will not permit the institution of vigorous sweating and purging or the withdrawal of blood followed by the intravenous administration of saline solution, indeed nothing can be done except to give a reasonably large quantity of fluid to increase the urin-

ary secretion, for within two weeks the urea usually returns to its original level. In the patient referred to it decreased to 46 mg in two weeks and remained at that figure.

A complication of coronary thrombosis which we have not seen mentioned in the literature, is cerebral thrombosis. It probably seldom occurs but since all of the patients have cardiac weakness, a low blood pressure, slowing of the rate of the circulation, and many of them have advanced arteriosclerosis—factors which underlie thrombus formation in cerebral arteries—we wonder why cerebral thrombosis does not occur often, especially in those patients who are slow in recovering from the acute attack. The symptoms arising in the course of the following case suggest thrombosis of a cerebral artery eleven days after the occlusion of a coronary artery occurred.

Case Abstract H. C., white male, 66 years of age, was admitted to the Lewis-Gale Hospital on December 15, 1930, complaining of substernal pain and a choking sensation. The pain began suddenly in the epigastrium four days previously, it increased in severity and it was not readily relieved by morphine. After the first day the pain was located chiefly under the sternum. When the patient was admitted to the hospital the pain was severe and it was accompanied by nausea and vomiting. All of the symptoms and signs, including a blood pressure reading of 96/68, indicated coronary thrombosis. The R-T segment of the electrocardiogram showed the modifications associated with thrombosis. According to the work of Barnes and Whitten¹ these changes were classified as of Type T₃, which would indicate that the infarction was in the posterior portion of the left ventricle in the region supplied by the right coronary artery in the average heart.

The pain recurred each day and morphine was given when required. As the persistence

of nausea and vomiting precluded the taking of fluid and solid food, 30 c.c. of 50 per cent solution of glucose was given by vein and 500 c.c. of saline and 5 per cent glucose by rectum daily. By the sixth day a slight improvement was noted in the quality of the heart sounds, the systolic blood pressure varied between 100 and 110 mm., his general condition was better, and the nausea was subsiding.

On December 20, one week after admission, he did not respond to questions, whereas before he had responded readily, his mind was not clear, although he was not unconscious, as he gave evidence of understanding questions and made an effort to talk, there was some difficulty in deglutition, motion and sensation in the right arm and hand, and to a less extent in the right leg, were diminished. Five days later the patient showed some improvement, his mind was more alert, his speech was fairly distinct, and he could move the arm and leg more easily. He died suddenly, probably from cardiac dilatation, on December 25. An autopsy was not permitted.

The mental haziness, the motor aphasia, the diminished sensory perception and motion in both right extremities indicated some disturbance in the circulation of blood in that part of the left frontal cerebral convolution with which the functions of speech and of motion in the right side of the body are associated. Since all the underlying factors of cerebral thrombosis mentioned above were present, and as improvement in these symptoms was observed in five days, we think there was a partial occlusion of a cerebral artery by a thrombus. It is quite possible that these symptoms were due to an embolus instead of the formation of a thrombus in the cerebral artery. The area of infarction in the myocardium may have extended to the endocardium, causing an inflammatory reaction with the formation of a thrombus, which may have been dislodged and carried by the blood to the brain.

If such a complication should occur, little if anything can be done about it, the clinician should continue to direct his attention chiefly to the heart and to the comfort of the patient. In the

case mentioned above we continued the same treatment the patient had been getting before the development of the cerebral symptoms

As in all other cardiac conditions, the possible use of digitalis must be considered in the treatment of coronary thrombosis. In this condition there is a slowing of the rate of the circulation with congestion in the lungs and in the general circulation, although edema rarely occurs. When the measures outlined above for relieving the pain, combating shock, supplying nourishment and gentle stimulation if required, are employed, the rate of the circulation increases as the myocardium regains its strength. In the majority of the patients it does not appear to be necessary to give digitalis during the acute stage. There is no evidence to show whether digitalis is harmful or beneficial soon after the occlusion of a coronary artery. Many clinicians do not advise giving this drug during the acute stage, for since digitalis increases both the force of the cardiac contractions and the intraventricular pressure during the contractions, it may cause a rupture of the myocardium in the area of infarction. We do not know that a case of rupture due to the use of the drug has been reported. On the other hand, digitalis may be beneficial in all cases since it is said to increase the coronary circulation and the patient's recovery depends upon an adequate circulation through the coronary arteries and their branches. It should certainly be used if the symptoms and signs of heart failure appear, or if a marked arrhythmia, either extrasystolic or fibrillatory develops. When these signs appear they are urgent enough

to warrant the intravenous injection of two to four c.c. of digitalin. The dose is calculated on a basis of one-third to one-fourth of a grain per pound of body weight, and may be repeated every two to three hours for three or four doses. If the patient has recently taken digitalis, smaller doses should be given. Subsequent doses may be regulated by the condition of the patient, but it is undesirable to reach the full therapeutic dose because of the danger of rupturing the heart or of producing toxic symptoms. We have employed the drug in this manner in two patients, watching them closely for any untoward effect, and as far as we can tell they were benefited by it. After the first few doses the intramuscular injection was substituted for the intravenous. Caution is necessary in giving digitalis soon after thrombosis occurs.

Aside from medication the administration of oxygen may sometimes be of value therapeutically. The retardation of the rate of the circulation leads to diminished oxygenation of the blood and to a deficiency in the supply of oxygen to the body tissues. This results in cyanosis, which is not marked in some cases and is probably dependent upon the slower passage of blood through the skin vessels rather than to anoxemia. In other patients cyanosis is a more prominent feature and anoxemia may exist, certainly it is favored by the presence of such factors as a slow rate of the circulation, much congestion in the lungs and some long standing pulmonary disorder, such as emphysema. By the administration of oxygen to such patients the re-oxygenation of the blood will be more com-

plete; the cyanosis will be diminished, the dyspnea will be relieved and the comfort of the patient will be increased

Absolute rest and quiet in bed to conserve the strength of the heart is of the greatest importance. Visitors should be forbidden or limited for several days following the attack. The physician should refrain from making an elaborate examination. Since the action of the heart is already encumbered, any movement of the body consequent upon a detailed physical examination increases the work of the heart unnecessarily. We can determine the condition of the patient by the quality of the heart sounds, by the character of the pulse and respirations, by the blood pressure readings, and by the condition of the abdomen. The patient should be spared the effort of feeding and turning himself in bed for two or three weeks, good nursing care is indispensable. His diet should consist of easily digested and nutritious food. During the early days of the attack the bowels are apt to become constipated as a result of large doses of morphine. It is better not to force any bowel movement for two days, then an enema may be given and one should be given daily thereafter. Laxatives should not be given until the patient is well along the road to recovery and then only in doses sufficient to produce gentle action. The patient should not have to use the bed pan more than once daily while he is in bed, slight constipation is a desirable feature.

THE LATE MANAGEMENT OF CORONARY THROMBOSIS

When the patient has recovered from the acute attack of coronary throm-

bosis, the next important consideration is the supervision of his habits of life in order to assist the heart in maintaining the circulation as near normal as possible. The time the patient may get out of bed, the extent of his activities, the use of digitalis and of other drugs which may improve the coronary circulation, and his general welfare are questions which require the utmost attention.

It is now well agreed that patients should remain in bed for at least five to six weeks for the area of infarction to heal, and that this length of time should be increased in proportion to the severity of the symptoms. This stay in bed is not sufficient for the heart to recover much of its reserve force, hence when the patient is allowed to get up he should spend only short periods of time out of the bed during the following two or three weeks. This permits the physician to see how the heart responds to the exertion. It should be remembered that the myocardium never fully recovers from the damage of infarction, and in some instances symptoms and signs of progressive failure of the heart appear soon after the patient gets up. Sudden death may occur at any time. As a rule, if convalescence from the acute stage is gradual, the myocardium regains its function sufficiently to withstand the extra work imposed upon it by the patient's getting out of bed.

When the patient is permitted more activity he should know the limitations his cardiac condition places upon him. Graduated exercises will serve a double purpose. They will enable the patient to discover how much effort he may put forth without feeling

pain, and they may possibly strengthen the heart muscle to some extent. The amount of exertion the patient can put forth without discomfort when he begins his exercise is no guide to what he will be able to do later. However, graduated exercises give him confidence in himself and since they enable him to take an intelligent interest in his welfare, he may be prevented from going to extremes, taking no precautions at all or considering himself an invalid. The amount of exercise allowed may be determined by the rate of the heart, the quality of the sounds, and whether the patient has any shortness of breath or pain referable to the precordial area. These indications also aid the physician in determining how much of his work he may resume. It is necessary to emphasize to the patient that he must rest lying down, a definite number of hours each day, the number of hours depending upon his condition.

The activities of some of the patients who survive an attack of coronary thrombosis must be very greatly curtailed since the restoration of the cardiac reserve force is insufficient to permit them to withstand much exertion. They often become discouraged because of their disability, some of them are prone to worry about themselves or their future, anxiety and fear of death will have a depressing effect upon them. If in the opinion of the physician an occasional laxity in restrictions may be allowed, it will help maintain the patient's morale. Clinical judgment again is an asset in aiding the physician to determine what is best for his comfort and happiness and for these, of course, no definite in-

dications can be given that will fit each case.

The majority of persons who survive an attack of coronary thrombosis will require digitalis soon after the acute stage is passed, or later in life. We have found that a large number of them, especially those who have had a severe attack, require it about the time they are allowed to get out of bed. Even though the heart seems to be maintaining the circulation adequately while the patient is lying in bed, we believe that the administration of digitalis at the time he is allowed to sit up strengthens the myocardium, improves the circulation and hastens the progress of the patient. When the drug is given, three to four grains of the powdered leaves each day until the signs of digitalization appear, will usually increase cardiac efficiency, then one and one-half grains given daily for as long a period of time as is necessary will usually maintain the efficiency. If this small dosage should not always be sufficient, it may be increased when symptoms and signs of decompensation appear, and decreased when the effect of the larger dose is obtained. This prolonged use of the drug increases the comfort of the patient, permits some increase in the range of his activities and rarely causes unpleasant symptoms. In all patients there are intervals when digitalis may be omitted and careful observation will determine when it should be taken again. There are intelligent patients who, after some experience, will learn to appreciate the early signs, either of too little or too much digitalis and they can guide their dose accordingly. It is interesting to observe that several

of our patients who required digitalis almost daily for twelve to eighteen months, could get along well without it after that time, while others required small doses for short periods of time.

In recent years a number of clinicians have employed the xanthine diuretics for their vasodilator effects in the treatment of heart conditions in which there have been attacks of pain. The drugs of this group most frequently employed are theobromine and its salts, and theophylline-ethylenediamine or euphylline, now known as amino-phyllin. Experiments have shown that these drugs dilate the coronary arteries, amino-phyllin possessing the greatest dilating effect. Smith, Miller and Graber³ showed that amino-phyllin increases the rate of perfusion of the intact heart from 40 to 90 per cent. The reports in the literature are unanimous in agreeing that patients who are subject to angina pectoris have the attacks less frequently and severely when taking these drugs at intervals over a long period of time, but that those who have had coronary thrombosis receive less benefit. The difference in the results obtained may be understood when we realize that the phenomena of angina pectoris can best be explained by a blood flow in the coronary vessels inadequate for the needs of the heart muscle at the moment, whereas, in coronary thrombosis there is obstruction to the flow of blood through the artery in which marked sclerosis is often found at autopsy. Obviously, we cannot expect beneficial results in these cases when the anatomic changes in the coronary arteries preclude much or any dilatation by drugs.

Our experience with amino-phyllin

has been limited to a few cases. We have given it to those patients whose initial pain continued for several days, and to other patients who had pain or tightness in the precordial area after they were allowed to resume some of their activities, but no beneficial effects were observed.

In the supervision of the patient's habits of life it is necessary not only to give attention to the manner in which the heart is functioning, but other matters pertaining to his well being must also receive attention. While stressing the importance of a rest period each day, the physician should see that the patient sleeps well each night. If there is any tendency toward insomnia we should, without hesitation, give hypnotics in sufficient doses to produce sleep. A bromide and chloral hydrate solution is the most satisfactory hypnotic, although some of the barbituric acid preparations such as adalin, amy-tal and luminal in moderate doses will act well and will not have a depressing effect, if they are not used for more than a week at a time.

Aside from the heart, the majority of these patients will more frequently complain of gastrointestinal disturbances than anything else. The patient should eat food which is easily digested. Those patients who have little or no trouble with their digestion should eat a normally balanced diet simply avoiding the foods that are digested with difficulty. Overeating should be avoided at all times. It is best for the patient if his weight is normal or near the normal. If he tends to gain weight rapidly, or if he is obese, the carbohydrates in his diet should be restricted. Many of the patients who

have had coronary thrombosis have also chronic cholecystitis. Some of them may have received medical treatment for that condition, before the thrombosis occurred, others give a history of it, but they have not received treatment. In either instance it is often necessary to prescribe a suitable diet and such drugs as are ordinarily employed in the medical treatment of cholecystitis. The response of these symptoms to this treatment is similar to that observed in other patients in that it varies, although it is usually satisfactory. Occasionally there are patients who are troubled with stasis of the intestinal contents in some portion of the intestinal tract, more frequently in the cecum or colon. This should receive appropriate treatment.

Sometimes it becomes necessary to give drugs that act as tonics, the indications for these will not be altered by the patient's having had coronary thrombosis.

SUMMARY

1 The rational treatment of coronary thrombosis depends upon a knowledge of the anatomical changes which occur in the heart following thrombosis, and of the pathological physiology accompanying these changes.

2 Morphine should be given in doses large enough and often enough to control the pain. Heat should be applied to the body of the patient. Stimulation with drugs should be avoided unless the heart sounds are very feeble and arrhythmic, the pulse is very small in volume or imperceptible, the respirations are irregular and cyanosis is prominent. Caffeine sodium

benzoate should then be given in small rather than large doses, and it should be continued as long as the condition of the patient requires it.

3 When nausea prevents the patient from taking an adequate amount of fluid and food, a small quantity of a concentrated solution of glucose should be given intravenously, and saline and glucose solution by rectum daily, and both should be continued until he can take a sufficient amount of fluids and food by mouth. Glucose is readily utilized by all the body tissues, and the saline not only prevents dehydration, but it will increase the secretion of urine which is especially desirable if the blood urea should rise to a high figure. When cerebral complications occur the patient should be kept as quiet as possible, the clinician should continue to direct his attention chiefly to the heart and the comfort of the patient.

4 It is probably better not to give digitalis soon after coronary thrombosis occurs unless signs of heart failure appear. When the indications for it arise it may be given in doses based on one-fourth to one-third of a minim per pound body weight. If digitalis is given it is better to discontinue it before the full therapeutic effect is obtained.

5 Other therapeutic measures of great value are. Absolute rest in bed until the patient is well past the acute stage. Good nursing care, a diet consisting of easily digested and nutritious food. Laxatives should not be given until the patient is well along the road to recovery, but an enema should be given daily. The administration of oxygen may be helpful to those pa-

tients in whom cyanosis is a prominent feature

6 After the patient has recovered from the acute attack, the most important consideration is the supervision of his habits of life so that the heart

may be spared any undue strain. When he may get up; how much activity he may be allowed, the use of digitalis and other drugs, his rest in bed each day and his general condition are questions that require much thought.

Paroxysmal Tachycardia Related to the Menstrual Period*†

By J HAMILTON CRAWFORD, M D, F A C P, LOUIS H SIGLER, M D,
and H FRUCHTER, M D, *Brooklyn, N Y*

PAROXYSMAL tachycardia is a disease of extreme interest in that so many factors in regard to it remain obscure. Although electrocardiography has enabled us to localize within narrow limits the region of the heart from which the paroxysms arise, no definite conclusions have been arrived at as to the mode of initiation and maintenance of the abnormal rhythm. Many causes have been described which were related, in different individuals, to the onset of the attacks, but the common factor which these possess still remains unsolved. In spite of this, however, it seems of value to record all possible etiological aspects in the hope that eventually a solution may be found. The following cases are presented as they show a relationship between menstruation and the onset of attacks.

REPORT OF CASES

Case 1 E K, a white female, age 42, was seen first in the Cardiac Clinic of the Long Island College Hospital on February 2, 1929, complaining of palpitation, precordial pain, weakness and dizziness. She stated that in 1924 she awoke one day to find that she could not move her arms and that her

legs were very painful to touch. She called her doctor who said that she had neuritis and prescribed for her. By the next day the pain had gone and movements were free. Later in the morning she developed a severe attack of palpitation and precordial pain which required injections for its control. She became constipated and had considerable abdominal distension, while the urine was scanty. Up to 1927 she had attacks almost every other week. At this time she separated from her husband and since then the paroxysms have recurred regularly every month. As a rule they precede the menstrual period by about five days. The present attack started three days before she attended the clinic.

The patient states that in the interval between attacks she can work as a waitress without discomfort. She has some dyspnea when she climbs stairs but none on walking on the level. She experiences no palpitation or precordial pain and edema is never present. There is no gastric distress and the bowels move three times a day. The menstrual periods take place regularly every 27 days. They last four days and are profuse but dysmenorrhea is only slight. She has had some hot flashes of late but the periods have not stopped.

Previous Illnesses Patient in childhood had measles, mumps, chicken pox, whooping cough, diphtheria, scarlet fever and pneumonia. There was no history of rheumatic fever, but she frequently suffered from tonsillitis and 'growing pains'. She denies syphilis or gonorrhea.

Family History Mother and father both died of apoplexy. Patient has three children alive and well. She had frequent induced

*From the Department of Internal Medicine, Long Island College of Medicine, Brooklyn, New York.

†Submitted for publication July 17, 1931.

abortions. She was sterilized in 1916. Patient had considerable marital difficulty before she separated from her husband. She drinks a considerable amount and smokes one package of cigarettes in two days.

Physical Examination Patient was a woman of nervous disposition weighing 153 pounds. There was no cyanosis or edema. The tonsils had been removed and there were full upper and lower plates of artificial teeth. The thyroid was not enlarged. The pulse rate was 198 beats per minute and the volume was small. The blood pressure was 120/100. There was marked precordial tenderness. The heart was definitely enlarged, the right border being 4.5 cm from the midsternal line in the fourth interspace and the left border 13 cm from the midsternal line in the fifth interspace. The sounds were closed in all areas. A_2 was short and snapping. There were no râles in the lungs and the liver was not enlarged. The urine showed a faint trace of albumin but was otherwise negative.

An electrocardiogram showed a tachycardia of supraventricular origin at a rate of 200 beats per minute. It was impossible to decide whether the tachycardia was of A-V nodal origin or whether 2-1 auricular flutter was present in which one wave was buried in the ventricular complex. There was slight right axis deviation. The T-wave was negative in Lead 3.

Treatment Vagal compression in the neck and ocular compression were without effect. Patient was ordered complete rest in bed and was given quinidine sulphate six grains every four hours.

Progress Notes The above attack stopped the day after she was seen in the clinic and the patient felt well again. The following week she was seen in the clinic. The pulse rate was 72 beats per minute and the blood pressure 120/80. The size of the heart remained the same and the sounds were closed in all areas, while A_2 was still accentuated. She was ordered to take quinidine sulphate, three grains three times a day, in order to prevent further attacks, but despite this the paroxysms recurred each month. The patient did not take the drug consistently, however, and was very irregular in her attendance at the clinic. On one

occasion on which she appeared at the clinic in an attack, digitalis was prescribed and the paroxysm ceased after she had taken four tablets of digitalis leaves, each containing $1\frac{1}{2}$ grains. Subsequently the patient attended the clinic at long intervals. The attacks continued to recur each month, but were controlled by rest and small quantities of digitalis. On March 11, 1931, she came to the clinic and stated that she was in the midst of an attack of greater severity than usual, which she had been unable to stop. This paroxysm had been present for three days. As her condition looked worse than on any previous occasion she was admitted to Long Island College Hospital. Marked dyspnea was present and there was some cyanosis of the lips and malar regions. Pretibial pitting was present to a slight extent. The temperature was normal. The pulse rate was 180 beats per minute while the heart showed the same findings as before. There were moist râles at the base of both lungs and there was also marked tenderness over the upper abdomen. The urine showed a trace of albumin but was otherwise negative. The blood chemistry was normal as was the blood count, the white blood cells being 8,100. The Wassermann reaction was negative. The electrocardiogram was identical with that taken in 1929 except that the T-wave was negative in Lead 2 as well as in Lead 3. Patient was given quinidine sulphate, six grains every four hours. On March 13, she developed an attack of acute pulmonary edema from which she recovered after phlebotomy and morphine sulphate, $\frac{1}{4}$ grain. All other medication was discontinued. The pulse rate remained the same until March 14, when it suddenly fell to 90 beats per minute, after which it gradually slowed to about 80 beats per minute. Recovery was rapid. On discharge the only abnormal finding apart from the cardiac enlargement was an occasional auricular extrasystole. The electrocardiogram showed nothing abnormal except slight right axis deviation. Patient was ordered to take quinidine sulphate, three grains three times a day. The following week the patient appeared at the clinic in another attack. She said that this was the only time for many years that an attack had recurred after

such a short interval. As no beds were available in hospital and as the symptoms were not as severe as with the last attack she was instructed either to go home to bed and take tablets of digitalis leaves, $1\frac{1}{2}$ grains three times a day, or to go to a City Hospital. Since then patient has not returned to the clinic and cannot be located.

Case 2 S M, a female 17 years of age, was admitted to the Coney Island Hospital on February 15, 1930, complaining of severe palpitation and precordial pain. The patient stated that she had had frequent attacks of this nature. The first attack preceded by two days her first menstruation at the age of $13\frac{1}{2}$ years, and since then she has had an attack practically every month at the time of the menstrual period. Only two attacks were unrelated to menstruation and both followed extreme excitement. At the onset of an attack the patient experienced a sensation of momentary stoppage of the heart. Likewise the cessation of the paroxysm was abrupt. Until the present attack the paroxysms have lasted only a few hours and as a rule a day of normal cardiac activity has intervened before the onset of menstruation. During a paroxysm the patient suffered from palpitation, precordial pain, and weakness, but as a rule dyspnea was not marked. Vomiting occurred on some occasions and sometimes caused the attack to terminate. In the interval between attacks the patient had no symptoms except slight dyspnea on exertion and at times precordial pain. The menstrual periods occur every twenty-eight days, last two or three days, and the patient does not suffer from dysmenorrhea.

The present attack began on February 13, but unlike the previous attacks, persisted longer. Signs of circulatory failure began to appear and in consequence the patient was removed to the hospital.

Previous Illness At the age of ten the patient fainted in school, and a physician, who was consulted, stated that she had heart disease. There was a history of repeated tonsillitis up to the age of $2\frac{1}{2}$ years, at which time tonsillectomy was performed, but there was no other history suggestive of rheumatic infection. She had measles and whooping cough in childhood. In 1924

a brother was referred to the clinic of Dr. Givan, at the Long Island College Hospital, suffering from congenital syphilis. In consequence of this, Wassermann tests were performed on all the family and our patient was found to have a two plus reaction. Arsphenamine treatment was instituted but the patient had a severe reaction after each of six injections so it was decided to discontinue the treatment. She was then re-referred to the Cardiac Clinic for further care. The clinic report showed that at that time she complained of severe precordial pain, dyspnea, and palpitation. The heart was enlarged and a systolic murmur was present at the apex while the second sound at the pulmonary area was much accentuated. The patient later developed a pre-systolic murmur at the apex. A diagnosis of mitral stenosis and insufficiency was made. In 1926 she left the clinic, the Wassermann reaction being still two plus, and she received no medical attention until her admission to the hospital.

Family History The parents and two sisters appear healthy. One brother has signs of congenital lues. The mother had one miscarriage.

Physical Examination The patient was a pale young girl with cyanosis of the malin region, lips, and extremities, but no edema. None of the stigmata of congenital syphilis was present. There was left lateral scoliosis. The thyroid was slightly enlarged, and the eyes showed slight prominence. There was marked pulsation of the vessels of the neck, both arterial and venous. The tongue was slightly furred and the teeth were in good condition. A few tonsillar tags were seen but these did not appear to be infected. The temperature was 102°F . The pulse was very rapid, of small volume, and capillary pulsation was present. The blood pressure was 114 systolic and 52 diastolic. The heart rate was 250 per minute. There was a diffuse pulsation all over the precordium and a systolic thrill, which was maximal over the mitral area, was felt over the greater part of this region. The apex was in the 6th interspace, 11.5 cm from the mid-sternal line. The measurements of the right and left borders of the heart in the fourth and sixth interspaces respectively were 15 cm.

and 120 cm On account of the rapidity of the heart it was difficult to decide whether any murmurs were present The second sound at the pulmonary area was accentuated The bases of the lungs showed a few moist râles, but there was no enlargement of the liver

Laboratory Data Red blood cells, 3,400,000, hemoglobin, 70 per cent, white blood cells, 18,200, with 80 per cent polymorphonuclear cells Urine sp gr, 1.032, acid, albumin, ++, sugar, negative, no casts The blood Wassermann reaction was negative on several occasions An electrocardiogram showed a heart rate of 250 beats per minute due to a tachycardia of A-V nodal origin The R wave was notched in leads 1 and 2 and slurred at the top in lead 3 X-ray examination of the heart showed a definite enlargement which was predominantly left ventricular The cardiac index was 0.56 There was slight prominence in the region of the left auricular appendix

Treatment Vagal compression in the neck and ocular pressure produced a slight slowing of the heart rate but failed to restore the normal rhythm On February 15, the day of admission, fluids were restricted to 1000 cc per day, an ice bag was applied to the precordium, tincture of digitalis, 20 minims, was given three times a day, and quinidine sulphate, three grains, was administered every four hours, day and night On February 16, the latter was increased to six grains every four hours, and on February 17, eight grains every four hours

Progress Notes The patient's condition remained the same until February 18, except for a slight increase in the size of the heart and the appearance of more râles at the bases of the lungs Both physical examination and electrocardiograms showed that a gradual slowing of the heart rate to 190 beats per minute took place during this period No symptoms of toxicity due to quinidine were observed At 8.30 p.m. on February 18, three days after admission, normal rhythm was suddenly resumed An electrocardiogram taken immediately after the resumption of normal rhythm showed normal sinus rhythm with a heart rate of 95 beats per minute The P-R interval was 0.13 sec R was slightly notched in leads

1 and 3 and slurred in lead 2 T was negative in all leads The temperature which had become much lower on the second day in the hospital now became normal There was a rapid improvement in the patient's condition The marked pulsation in the neck and in the precordial region disappeared, although a diffuse pulsation was still present in the region of the apex The size of the heart decreased, the left border being 10.5 cm from the midsternal line in the sixth interspace It was now possible to analyse the character of the heart sounds At the mitral area the first sound was preceded by a presystolic rumble and followed by a loud systolic murmur, while the second sound was followed by a slight diastolic murmur Just above the apex the second sound was reduplicated At the aortic area the sounds were faint, but in the second and third left interspaces, close to the sternum, a diastolic murmur was heard which was faintly transmitted down to the lower end of the sternum The râles at the lung bases rapidly disappeared

An electrocardiogram taken on February 28, just before discharge from hospital showed normal sinus rhythm with a heart rate of 85 beats per minute The P-R interval was 0.13 sec R was notched in lead 1 The R-T interval was curved and slightly depressed in leads 1 and 2 while T was negative in lead 3 At this time the basal metabolic rate was estimated and was found to be normal

The patient was discharged from the hospital with instructions to take quinidine sulphate, three grains, three times a day, for three days before the menstrual period However, about four days before the next period the patient, as a result of excitement, developed an attack which lasted several hours She was then told to take quinidine for a week previous to menstruation, but on the day preceding this period she had another attack which lasted ten minutes At the time of the next period an attack, which lasted twenty-four hours, took place two days preceding menstruation despite the administration of quinidine Quinidine was then given continuously in the same dosage, since which time there has been no recurrence

DISCUSSION

The outstanding feature, in these cases, is the relationship of the onset of the paroxysms to the menstrual periods. References to menstruation as one of the causal factors in precipitating attacks of paroxysmal tachycardia are infrequent. Vaquez and Pezzi¹ reported a case of paroxysmal tachycardia in a woman, with no evidence of organic heart disease, in whom the attacks were always related to the onset of menstruation. Paroxysms did not occur at every period but gradually increased in frequency and duration until the menopause was reached when they recurred at short intervals. Savini² studied a series of cases of this nature and concluded that the thyreo-genital systems play an important part in the production of attacks of paroxysmal tachycardia. He believes that these systems are mutually antagonistic, i.e., hypogenitalism produces hyperthyroidism which then tends to induce paroxysmal tachycardia. He states that attacks commonly start at puberty or the menopause and in the interval are related to the menstrual periods. Even in individuals in whom the attacks occur unrelated to menstruation more severe paroxysms are experienced if they occur at this time. He states that cases were aggravated by the administration of thyroid extract and were relieved by ovarian extract in women or by testicular extract in men. We feel, however, that at least the latter statement is contrary to the general experience while the hypothesis as a whole lacks adequate proof. Martinez³ studied thirty-one cases and he found that twenty-one of these had organic or functional disease of the

sympathetic or endocrine systems, either gross thyroid disease, genital disease, or indications of a disequilibrium of these systems. The determining factor in the production of the attacks was, as a rule, the prodromal symptoms of the menses but in some instances it was due to a delay in the onset of menstruation. Geraudel⁴ described a case in which attacks of paroxysmal tachycardia started at puberty and recurred every month at the time of the period. Lutier⁵ also reported the case of a young woman who suffered from exophthalmic goiter with irregular menstruation, in whom the first attack took place on the eve of a period, while subsequent paroxysms occurred most often at the time of menstruation. We have recently seen a young woman who was subject to attacks of paroxysmal tachycardia at long intervals and who showed no signs of organic heart disease. This patient became pregnant and since then the attacks have become more frequent and severe. Meyer, Lackner and Schochet⁶ have described two cases which they have studied and six cases from the literature, in whom attacks of paroxysmal tachycardia took place either during pregnancy or labor. One case was subject to attacks before she became pregnant, but there was an increase in their frequency during the pregnancy.

The causes which produce attacks of paroxysmal tachycardia are many and often obscure. There seems little doubt, however, that in our cases the provocative factor was the changes produced in the body by menstruation. It seems doubtful whether the thyroid in the absence of obvious thyroid dis-

ease, as in these cases, has as much responsibility for the attacks as some of the authors quoted above seem to think. It seems to us more probable that the attacks were due to some alteration in the activity of the sympathetic nervous system at the time of menstruation. The mechanism by which a change in the action of the sympathetic nervous system on the heart could induce an attack of paroxysmal tachycardia is at present unknown. It is possible that it may increase the sensitivity of some focus outside the sino-auricular node so that it emits impulses which control the heart. Or it may be that it causes an extrasystole which strikes the heart in a critical phase so that a circus movement is initiated and thus the abnormal rhythm perpetuated. Further evidence in favor of an alteration in the activity of the sympathetic system, as a cause of paroxysmal tachycardia, is that in many individuals, subject to attacks of this nature, the precipitating factor is excitement. On the few occasions in which the attacks in the second patient were unrelated to menstruation the provocative factor was great excitement, while in the first case the attacks were much more frequent when marital difficulties were present.

It is doubtful how great a part the pathological processes in the hearts of these patients played in the causation of the attacks. It is well known that paroxysmal tachycardia occurs in some cases of organic heart disease. On the other hand many who present no evidence of organic heart disease suffer from these attacks while in only a relatively few cases of organic heart disease do they occur. It may be that pathological changes in the heart predispose to some extent to the paroxysms but it seems as if some other influence were the important factor in initiating the attacks. In the cases presented the evidence of the relation of the onset of the paroxysms to menstruation is very striking and one feels that this provided the necessary stimulus.

SUMMARY

Two cases of paroxysmal tachycardia of supraventricular origin are described in one of which the attacks commenced at puberty and recurred at each subsequent menstrual period. In the other the paroxysms commenced later in life. In the early stages they occurred at frequent intervals, but for a period of years they have almost invariably had a definite relation to the menstrual period.

The Coincidental Occurrence of Diabetes Mellitus and Pernicious Anemia*†

Report of Two Cases

By CHARLES SHOOKHOFF, M D, *Brooklyn, N Y*

DIABETES mellitus is mentioned by Giffin and Bowler¹ as being one of the diseases which may be associated with anemia. Joslin² in a series of six thousand diabetics observed five instances in which diabetes mellitus and pernicious anemia co-existed. Adams³ found three such cases in a five year period, during which time two thousand patients with diabetes mellitus and one thousand patients with pernicious anemia were observed. Wright⁴ found two instances out of 475 patients with diabetes mellitus and 84 patients with pernicious anemia. Goudsmit⁵ reports five cases out of a total of 1063 cases of diabetes and 379 cases of pernicious anemia observed at the Netherland Clinics. Other instances of the coincidental occurrence of these diseases have been reported by Parkinson,⁶ Yong (cited by Joslin², Schumann⁷, Arntzen⁸, Hitzrot⁹, Berghausen¹⁰, Meulengracht¹¹, Bowen¹², and Baumgartner¹³). Recently Root¹⁴, in a résumé of this subject gathered together 48 cases, thirteen of which were found out of seven thou-

sand diabetics. These latter figures include Joslin's case.

The cases reported below are of interest not only because of the rarity of the concomitant occurrence of diabetes mellitus and pernicious anemia, but also because it is thought that with the increase in the number of case reports in which the specific methods of treatment for both the diabetes mellitus and pernicious anemia have been used, a better idea as to the possible relationship or the effect of the presence of one disease on the course of the other disease may be obtained.

CASE REPORTS

Case I Female, white, 58 years of age, was first seen in December, 1928.

Complaints Weakness, loss of appetite, loss of sixteen pounds in one year, sweats, hot flushes, and edema of the ankles, one month duration.

History Mother and father are dead, age and cause unknown. One brother has diabetes and high blood pressure and one sister has a high blood pressure. Patient had measles at five years of age and no other illnesses. Menopause at the age of forty-nine years.

Physical Examination Well nourished female of the sthenic type. Weight 166½ lbs., height 64¼ ins. Definite glossitis present. Eyes reacted to light and accommodation. Lungs normal. Circulatory system: blood pressure 160/75; regular sinus rhythm.

*From The Jewish Hospital of Brooklyn and The Greenpoint Hospital of Brooklyn, N Y.

†Received for publication, June 1, 1931.

basilar vessel line percussed as widened to the left, A-2 accentuated and musical, definite aortic configuration with an enlargement of the left ventricle, heart sounds of good quality, no carotid sheath reflex vagal reaction noted, the left leaf of the diaphragm high standing Abdomen spleen palpable one finger below the costal margin, abdomen otherwise negative Reflexes normal Varicose veins of lower extremities, no edema No loss of vibratory sense

Laboratory Data Urinary sugar 4.65%, fasting blood sugar 160 mgms per 100 cc of blood serum, Blood hemoglobin, 60%, red blood cells, 1,400,000, white blood cells, 4,400, 72% polymorphonuclears, 26% lymphocytes, 1% eosinophiles, macrocytosis

Diagnosis Essential hypertension, diabetes mellitus and a possible pernicious anemia

Patient became sugar free on diet and twenty units of insulin daily, and after having been given the equivalent of 200 grams of liver daily her blood count was 3,100,000 with 65% hemoglobin

In June, 1929, the patient reappeared with symptoms due to increasing anemia She was admitted to the Jewish Hospital of Brooklyn complaining of increasing weakness, hot flushes, profuse sweats, edema of the legs, pain, weakness and parasthesias in both lower extremities

Physical Examination There was now a marked lemon-yellow pallor which had increased since the last time she was observed Glossitis Tonsils and pharynx slightly infected Lungs a few crepitant râles at both bases which disappear on breathing Heart as on previous examination, blood pressure 155/80 Abdomen the liver was one fingerbreadth below the costal margin, hard, not tender, spleen palpable Reflexes slightly diminished The vibratory sense was definitely diminished in the right leg and entirely lost in the left

Laboratory Data Urinary sugar, 1%, fasting blood sugar, 166 mgms to 100 cc blood serum, CO₂ combining power, 53.6, urea nitrogen, 12.5, sugar tolerance

	8 30	9 30	10 30	11 30
Blood	171	410	444	410
Urine	0	0.25	6.6	10%
Cholesterol	256 mg			

Blood hemoglobin, 55%, red blood cells, 2,180,000, white blood cells, 4,800, 45% polynuclears, 47% lymphocytes, 5% mononuclears, blood platelets, 120,000, bleeding time one-half minute, coagulation time two minutes, anisocytosis and poikilocytosis, polychromasia marked, macrocytosis, one megaloblast in 100 white blood cells, reticulation, 5%, icteric index, 93, Van den Bergh, indirect, one unit Gastric analysis free acid, 5, 0, 0, 3, total acidity, 10, 28, 42, 45 Wassermann and Kahn tests negative Temperature and pulse rate were within normal limits

Treatment Diet 60 grams carbohydrates, 60 grams proteins, 70 grams fats Ten units insulin twice a day Transfusion, 240 cc, group "O" donor The equivalent of 300 grams of fresh liver was given daily

The patient became sugar free in a short time and left the hospital against advice While the diabetes seemed to be controlled, the anemia did not improve and a blood count on June 30, 1929, showed a hemoglobin of 58% and red blood cells, 2,100,000 At this time she developed an upper respiratory infection, a herpes labialis and a febrile reaction which lasted for a few days We again advised hospitalization and she was admitted to the Greenpoint Hospital on July 2, 1929 Her physical findings on this admission were not different than on previous examinations, except that she looked more anemic Blood pressure was 160/80

Laboratory Data July 3, 1929 urine negative, fasting sugar, 77 mgms, blood urea, 28, Wassermann, negative Blood hemoglobin, 50%, red blood cells, 2,110,000, white blood cells, 4,900, 52% polynuclears, 40% small lymphocytes, 8% transitionals Gastro-intestinal roentgenological examination revealed no abnormalities

On July 9, the patient was given a transfusion of 250 cc of blood, group "O" donor Liver extract was given also, and she continued with her insulin She was discharged from the Hospital on July 18, 1929, sugar free A blood count on November 13, 1929, showed hemoglobin, 80%, and red blood cells, 4,230,000

Subsequent communications from patient and her physician informed us that while her anemia seemed to remain under control

on the liver diet, more insulin was required to control her diabetes

COMMENT

The diagnosis of diabetes is definite. The diagnosis of pernicious anemia is based on the blood picture.

(A) High color index, macrocytosis, etc., high icteric index, positive indirect Van den Bergh test, and relative lymphocytosis,

(B) the clinical findings of glossitis, cord symptoms, large spleen, lemon-yellow color,

(C) absence of gastro-intestinal abnormalities, bleeding or any other cause for the anemia.

This patient's reaction to treatment is somewhat similar to Hitzrot's⁹. The diabetes was at first more easily, and her anemia less easily, controlled. Subsequently, after two transfusions and liver therapy, the patient entered a remission, but the diabetes became more pronounced and more insulin was required to control it.

Case II Female, white, age 61 years. Admitted to the Jewish Hospital of Brooklyn, surgical service of Dr. William Linder, on September 18, 1929.

Chief Complaints Attacks of severe pain in the right upper quadrant, temperature, nausea, loss of appetite, constipation, loss of sixty pounds in eight months.

History Family history is negative. Patient had a dry pleurisy in 1922, and has had diabetes for eight years.

Present Illness Eight months ago she suffered her first severe attack of pain in the abdomen, radiating to the right upper quadrant, has since had repeated attacks, particularly at night. Two months ago after a particularly severe attack, jaundice and clay colored stools were noticed. Patient has been losing weight, has a poor appetite and has been complaining of increasing weakness.

Physical Examination Temperature 101°. Female with a yellowish pallor, apparently has lost some weight. Eyes react to light and accommodation. Glossitis present. Heart and lungs negative. Abdomen some tenderness in the right upper quadrant, liver and spleen not palpable. No abnormal neurological findings.

Laboratory Data Urinary sugar 12%, fasting blood sugar, 241 mgs. sugar in 100 c.c. blood serum, CO₂ combining power, 50.7. Blood hemoglobin, 45%, red blood cells, 900,000, white blood cells, 8,600, 74% polymorphonuclears, 20% lymphocytes, 6% large mononuclears.

Treatment was instituted by giving seven units of insulin three times a day and 500 c.c. of a 5% solution of glucose intravenously daily.

On September 21, the hemoglobin was 37%, red blood cells, 1,300,000, white blood cells, 2,500, 67% polymorphonuclears, 26% lymphocytes, 2% mononuclears, 1 eosinophile, 1 basophile, myelocytes, 2, metamyelocytes, 0.666, myeloblasts, 0.33, anisocytosis, polychromasia and poikilocytosis marked, many macrocytes, few giantocytes, reticulation, 3%, icteric index, 7.2, bilirubin plus, indirect, one unit blood.

On September 23, urinary sugar, 0.5%, no acetone, fasting sugar 120 mgs. to 100 c.c. blood serum, CO₂ combining power, 57.4. On September 24, a transfusion of 500 c.c. blood, group "O" donor, was given and liver extract, one vial every three hours. On September 25, a 5% glucose retention enema, was ordered, six ounces three times a day. On September 29, the patient had a fasting sugar of 150 mgs. per 100 c.c. blood serum, CO₂ combining power, 60.2. On September 30, gastric analysis showed no free hydrochloric acid. The patient was given dilute hydrochloric acid, twenty mms. between meals.

At this time temperature had dropped to normal. The patient was sugar free on a diet of 100 grams carbohydrates, 60 grams proteins, and 150 grams fats. No further gall bladder attacks were experienced. Hemoglobin was 45%, red blood cells, 2,070,000, reticulation, 1%.

On October 7, 1929, the urine was normal, no acetone. Blood examination showed

55% hemoglobin and red blood cells, 3-040,000 There had been no further gall bladder attacks and the patient was discharged

Final Diagnosis Pernicious anemia, diabetes mellitus, chronic cholecystitis, and chronic cholelithiasis

This patient was subsequently readmitted to the Hospital for a blood transfusion because of her failure to react to liver therapy At this time her diabetic condition was well under control

COMMENT

The diagnosis of both the diabetes mellitus and pernicious anemia is clear in this case

The diabetes seemed to respond very readily to insulin despite a fairly liberal diet, while the anemia did not respond as well to liver therapy Further blood transfusions were necessary at a time when the diabetic condition was under control

DISCUSSION

In a study of anemia associated with pancreatic disease, Chvostek¹⁵ concluded that severe anemias dependent only upon disease of the pancreas may exist The onset of the anemia, the absence of cachexia, the absence of symptoms referable to gastro-intestinal disease, and finally, the presence of lesions in the pancreas only, at post-mortem, were the reasons for the assumption of a pancreatic anemia He thought such anemias were hemolytic in nature and suggested the possibility of a pancreatic disease being the underlying factor in some cases of pernicious anemia

Giffin and Bowler¹ stated that glycosuria, if not true diabetes, may be due to severe anemia. Meulengracht and Iversen¹⁶ found in pernicious ane-

mia an increase in the blood sugar levels and a delay in their return to normal Strauss¹⁷, however, found no glycosuria in six cases of pernicious anemia after the administration of 100 grams of glucose

Greene and Conner¹⁸ showed that liver function in the primary anemias is not often disturbed They found no retention of phenoltetrachlorophthalein in nine out of twelve cases of pernicious anemia studied In two patients a very slight retention of dye was noted There was a definite diminution in excretion of the dye in only one patient

These observations do not clarify the situation Pancreatic disease may cause anemia, anemia may cause disturbance of carbohydrate metabolism On the other hand, severe pancreatic disease without anemia is frequently observed, while patients with severe anemia may have a normal carbohydrate metabolism and normal pancreatic and liver function

Both diabetes mellitus and pernicious anemia have at present a specific therapy, a therapy dependent probably in both instances on an insufficiency of internal glandular secretion The results of the use of these specific forms of treatment in uncomplicated cases have been excellent

H Blotner and W B Murphy¹⁹ found that liver, which had previously been contra-indicated as a food in diabetes because of its high glycogen content, when administered to diabetic patients, showed a very beneficial effect on their blood sugar curves They showed that certain liver fractions which are ineffective in the treatment of pernicious anemia have a definite

beneficial effect on the blood sugar curves of diabetic patients. Von Varga²⁰ obtained good results with insulin and combined liver and insulin therapy in eight cases of severe pernicious anemia. He believed that insulin was certainly not contra-indicated in severe anemias. Adams³ observed a definite decrease in the effectiveness of insulin in lowering the blood sugar in profound anemia. No high liver diets were then given.

The response to specific therapy in those patients in whom the two diseases co-existed varied widely. The anemia with marked cord symptoms preceded the diabetes in Baumgartner's¹³ patient by one year. The diabetes came at a time when the anemia was well under control. There was a marked improvement in both diseases upon the use of liver, insulin and diet. Yong's² patient had diabetes for four years and had been given as high as ninety units of insulin per day before the primary anemia was discovered. She responded nicely to the combined treatment. Arntzen's⁸ patient showed a decided improvement in both the diabetes and pernicious anemia on the combined treatment. Goudsmit's⁵ patient showed an increase in her sugar tolerance when put on a liver diet. The diabetes was mild or not in evidence in Hitzrot's⁹ patient during the height of the anemia, but reappeared during the remission of the pernicious anemia which had responded to a Minot-Murphy regime. In our Case I the diabetes seemed to respond readily to treatment, diet and insulin, while the pernicious anemia was more difficult to control. Not much improvement in the anemia

was noted on concentrated liver diet until after two blood transfusions were given, from then on there was a definite improvement on liver feedings. After the anemia was controlled the diabetes became more severe and more insulin and a stricter diet became necessary. Meulengracht's¹¹ patient had pernicious anemia, hyperthyroidism and diabetes mellitus. The anemia reacted well to the liver diet, and at the height of her remission the patient complained of thirst and loss of weight and was readmitted to the clinic with a marked diabetes. While the anemia was controlled by the liver therapy, the diabetes was not so easily managed, at a time when this patient had a hemoglobin of 91 per cent and 4,200,000 red blood cells, she had a fasting sugar of 309 mgs of sugar per 100 c.c. of blood serum. Bowen¹² found no evidence of a blood sugar lowering action of liver in the case he reported. The diabetes in his patient became much more severe during a two month period during which she was under observation. Berghausen's¹⁰ patient, a female 70 years of age, had had diabetes since 1913, symptoms of the pernicious anemia appeared in 1928, liver therapy or antidiabetic treatment had no effect upon the pernicious anemia. In our Case II the diabetes had existed for eight years prior to the onset of the pernicious anemia and was always easily controlled by diet and later by insulin. The diabetes continued mild after the onset of the pernicious anemia. The anemia however did not seem to react as well to liver diet and transfusion as is usually the case with uncomplicated pernicious anemia.

Root¹⁴ states that good results were obtained with insulin, liver, or a potent substitute, and a diet rich in vitamins.

The rarity of the occurrence of the combination of these two diseases which individually are common, this maze of partially contradictory experimental and clinical data and response to specific treatment, makes tenable the supposition that these diseases are not inter-related and that their occurrence in the same patient is entirely coincidental.

Diabetes is frequently associated with, and by some observers is considered the cause of, coronary sclerosis. Angina pectoris on that pathological basis is not an infrequent symptom in diabetes. Herrick²¹ and others have described an angina pectoris symptom complex in patients with severe anemia, and ascribed it to the insufficient and poor cardiac muscle blood supply. It is of interest in the light of these facts, that in none of the cases reported in which both diabetes mellitus and pernicious anemia co-existed has any mention been made of an angina pectoris symptom complex being present.

SUMMARY

Two cases of the coincidental occurrence of diabetes mellitus and pernicious anemia are reported, one in whom the diabetes antedated the pernicious anemia by eight years, and the other in whom both diseases were found simultaneously. Liver and insulin were given to both patients. In Case I the diabetes became more severe at a time when the patient had entered into a remission of the anemia, in Case II the anemia did not respond well to specific treatment, while the diabetes was always easily controlled by insulin and diet.

No relationship seems to exist between pernicious anemia and diabetes, nor does the presence of one disease affect the course of the other in a characteristic manner.

Results of specific therapy, when a sufficiently large number of patients having both diseases have been treated, may give some information as to the relationship of these diseases. In the few cases so far studied uniform results have not been obtained.

We wish to thank Dr. William Linder for his kindness in permitting us to report Case II.

The Significance of Meningeal Permeability*†

By S. KATZINILBOGIN, M.D., F.A.C.P., *Baltimore, Md.*

BY "meningeal permeability" one designates the function regulating the exchanges between the general circulation and the cerebrospinal fluid. In recent literature this function is commonly described under the term "hematoencephalic barrier" or "barrier" between blood and fluid.¹ This new terminology² appears to be the more appropriate one, for, according to the prevailing, if not unanimous opinion, not only the meninges, but also various other structures of the cerebrospinal system and particularly the choroid plexus, take part in the function which has been inadequately ascribed to the meninges exclusively.²

The subject of this communication offers a wide range of topics which may be of interest to the biologist at large. For the discussion of to-day I chose two topics which, I think, deserve the attention of the medical man. These topics are: First, the diagnostic value of the "meningeal permeability." Second, its significance from the standpoint of therapeutics. With regard to diagnosis, it may be asserted that the actual knowledge on the exchanges be-

tween blood and cerebrospinal fluid proves to be helpful, in allowing a better approach to an adequate evaluation of the composition of the fluid. In a personal contribution to this subject, I found that the increase of the glucose content in the blood of rabbits, induced either by intravenous injections of glucose or by hypodermic administration of adrenalin, is followed by a rise of glucose in the fluid.³ Certain clinical observations on the distribution of glucose between blood and fluid are no less demonstrative. It is common knowledge that in the periods of epidemic encephalitis in 1917 to 1921, hyperglycorachia was commonly considered an important symptom of this disease.⁴ Subsequent determinations of sugar in blood and fluid withdrawn simultaneously in encephalitis and in various other diseases have, however, demonstrated that in a great many cases hyperglycorachia is proportionate to hyperglycemia,⁵ in these cases the high fluid glucose is evidently of no more significance than the high blood glucose itself. From these experimental and clinical investigations the following inference may be made: The amounts of glucose and, suggestively, of other diffusible components of the cerebrospinal fluid should not be estimated *per se* as absolute values, but as compared to the concentration

*Presented at the Fifteenth Annual Clinical Session of The American College of Physicians, March 27th, 1931, Baltimore, Md.

†From the Henry Phipps Psychiatric Clinic (Department of Internal Medicine), Johns Hopkins Hospital, Baltimore, Md.

of these components in the blood. On the other hand, certain data available in the literature have brought to light the following concept: various pathological conditions, mainly those associated with meningeal involvement are accompanied by an increase of the barrier permeability.⁶ In a personal study on the therapeutic effects of aseptic meningitis in epidemic encephalitis, provoked by intraspinal injections of casein, a distinct increase of the permeability to nitrate given by mouth was found, an increase which appeared to parallel the meningeal congestion, if not to follow proportionally, its intensity.^{7, 8} These findings suggest the contention, that discrepancies between the contents of diffusible components in blood and fluid may be plausibly ascribed to an altered function of the hematoencephalic barrier. Finally, in synthesizing the data so far recorded, I feel justified in venturing the following conclusion: Both experimental and clinical investigations contribute strongly to the view, that the concentration of the diffusible elements of the cerebrospinal fluid depends partly on their concentration in blood, and partly on the permeability of the "barrier" between blood and fluid.

For diagnostic purposes the function of the barrier has been tested, in the last three decades, in two ways, which have the common character of investigating the passage from the general circulation into the cerebrospinal fluid. The passage of blood constituent, such as hemolysins (Kafka and Weil), urea, sugar, chlorides (Derrien), syphilitic antibodies (Dujardin) and of substances introduced into the general circulation, such as nitrate (Mestre-

zat) iodine (Sicard, Osborne), uranine (Kafka, Schonfeld),⁹ etc. These tests have rendered service in determining an increased permeability in various pathologic conditions of the cerebrospinal system, particularly in those associated with involvement of the meninges. These tests are however charged with failure to give direct information as to normal or decreased permeability. The bromide permeability test devised by Walter⁹ six years ago is credited with filling this gap, that is, making possible the study of the normal and decreased, as well as the increased function. The test is performed by the following procedure: The subjects are given sodium bromide by mouth, 06 per kilogram weight, in twenty-four hours for five days. On the sixth day lumbar and venous punctures are performed successively and the content of bromide is determined in both blood and fluid. In accordance with most investigators, the normal ratios between the amounts of bromide in blood and fluid, called permeability quotients, lie within the limits of 2.9 to 3.3. These figures were considered normal standards in the studies so far carried out in this clinic. The bromide permeability test was used in various diseases, such as nephritis, diabetes, tuberculosis, skin diseases, etc., rather sporadically (Sunderhauf, Leopold). The bulk of studies is to be found in nervous and mental diseases. Perusal of the literature gives the distinct impression that the permeability of the barrier between blood and cerebrospinal fluid is raised in organic psychoses, particularly in general paresis and cerebral arteriosclerosis; that it is diminished in schizophrenia and within nor-

mal limits in manic depressive patients² The results obtained in a study of 188 patients, carried out in the Phipps Clinic, in collaboration with the City Hospital, are somewhat different The graphic presentation of our findings shows the following essential features (Chart I):

1 In each psychotic group the prevalent number of cases has a normal permeability It is worth noting that the percentage of normals is strikingly high in organic psychoses and in schizophrenia, that is, in the two psychotic groups in which, as mentioned above, an essentially abnormal permeability was found by most investigators

2 In our experience, however, an increased permeability was observed more frequently in organic psychoses, than in any other psychotic group, and a low permeability was found in a relatively high percentage of cases with schizophrenia, as compared to organic psychosis Thus, according to our findings, one may speak of a certain tendency to an increased permeability

in organic psychoses, and a decreased one in schizophrenia Besides, it should be added that similar tendencies are equally marked in the other two psychotic reaction types, namely, in affective psychosis and in mental deficiency

Walter's bromide test has also been studied in epileptic patients Out of 87 cases, a distinctly increased permeability was found in only twelve (13.8 per cent) A moderate rise above the normal standard was observed, however, much more frequently, namely in 24 out of 87 cases (27.6 per cent) Thus obvious tendency to an increased permeability in epilepsy, presents an interest when confronted with the frequent observation of an increased permeability in organic diseases of the cerebrospinal system

In the light of the results obtained with the bromide test, which revealed a tendency to an abnormal permeability in various psychotic groups and in epilepsy, it seemed of interest to test by other procedures, the function of the barrier in the same diseases The question arose whether the abnormal

CHART I

behavior of the barrier is specific to bromide, or whether this behavior is conditioned by factors proper to the diseases, and may also be brought about by other methods. The problem of the distribution of calcium between blood and cerebrospinal fluid attracted my attention for the following reasons. The function of the vegetative system is assumed to be closely connected with calcium (Kraus, Zondek). On the other hand the vegetative system takes a conspicuous part in the modern literature on nervous and mental diseases. The calcium studies were carried out on one hundred and thirteen patients belonging to the four psychiatric reaction types mentioned above. Blood and cerebrospinal fluid were withdrawn at the same time for the determination of calcium in both blood and fluid. Considering, in accordance with other investigators, that the normal ratios, fluid-Ca/blood-Ca, expressed as percentage are to be found within 45 and 55, our results may be summarized as follows (Chart II)

1 Abnormal figures were found in

a small number of cases, namely in nine out of the 113 cases

2 In manic depressive patients and in mental deficiency cases the ratios are within normal limits

3 Increased ratios, fluid-Ca/blood-Ca, were observed in five out of forty-two cases of organic psychosis

4 In the schizophrenic group ratios below normal were found in four out of forty cases

These findings show that the distribution of calcium between blood and fluid cannot yield any help in the diagnosis of the diseases which were investigated. It is interesting to note, however, that the passage of calcium from blood into fluid follows the trend of bromide. It shows, as does the bromide test, that there is a tendency to an increased permeability in organic psychoses, and a low permeability in schizophrenia.

Our calcium studies have also been pursued in a series of 86 epileptic patients from the Springfield State Hospital. It may be mentioned in passing, that these studies, in addition to the

CHART II

mal limits in manic depressive patients² The results obtained in a study of 188 patients, carried out in the Phipps Clinic, in collaboration with the City Hospital, are somewhat different The graphic presentation of our findings shows the following essential features (Chart I)

1 In each psychotic group the prevalent number of cases has a normal permeability It is worth noting that the percentage of normals is strikingly high in organic psychoses and in schizophrenia, that is, in the two psychotic groups in which, as mentioned above, an essentially abnormal permeability was found by most investigators

Considering, in accordance with other investigators, that the normal ratios, fluid-Ca/blood-Ca, expressed as percentage are to be found within 45 and 55, our results may be summarized as follows (Chart II).

I Abnormal figures were found in

a small number of cases, namely in nine out of the 113 cases.

2 In manic depressive patients and in mental deficiency cases the ratios are within normal limits.

3 Increased ratios, fluid-Ca/blood-Ca, were observed in five out of forty-two cases of organic psychosis.

4 In the schizophrenic group ratios below normal were found in four out of forty cases.

These findings show that the distribution of calcium between blood and fluid cannot yield any help in the diagnosis of the diseases which were investigated. It is interesting to note, however, that the passage of calcium from blood into fluid follows the trend of bromide. It shows, as does the bromide test, that there is a tendency to an increased permeability in organic psychoses, and a low permeability in schizophrenia.

Our calcium studies have also been pursued in a series of 86 epileptic patients from the Springfield State Hospital. It may be mentioned in passing, that these studies, in addition to the

CHART II

problem of meningeal permeability, also contribute to the discussion of the assumed relationship between epilepsy and tetany. The ratios, fluid Ca/blood Ca, were found to be within the limits of 46 to 65, instead of within the normal figure of 45 to 55. Ratios slightly above the normal standards were found in seven cases, and distinctly above the normal in four cases. The high ratios in eleven out of 86 cases, and no cases with ratios below normal, suggest that there is a tendency in epilepsy to an increased permeability of the "barrier" to calcium, a tendency which appeared to be more accentuated when the bromide permeability test was used.

The therapeutic significance of the "meningeal permeability" lies in the fact, that it takes a prominent part in the theoretical considerations, aiming to justify certain therapeutic procedures, which have had a great vogue in the last few years. The endolumbar treatment should be mentioned first. In epidemic encephalitis, autoserum, serum of convalescents, specific vaccine of Levaditi, and casein have been used for endolumbar injections.⁸ It has also been claimed that tabetic pains, and delirium tremens have benefited by intraspinal injection of bromide.¹⁰ Finally, attempts have been made to treat schizophrenia with intrarachial injections of horse serum.¹¹ The theory of the intraspinal treatment is based on the following two conceptions. (1) The cerebrospinal fluid is the intermediary body through which the exchanges between the general circulation and the nervous system takes place. This view is derived from the experimental investigations showing

that, among various substances introduced into the general circulation, only those which could be detected in the cerebrospinal fluid, have also been found in the nervous tissue. These findings lead to the belief that the effect of a drug on the nervous system is conditioned by its presence in the cerebrospinal fluid. (2) The other conception has a bearing on the function of the barrier between blood and fluid. This function is, generally speaking, an interfering, or, to say the least, a selective one with regard to the passage into the fluid of substances introduced into the general circulation. Using the intraspinal way, one aims to insure the contact of the drugs with the nervous tissue.^{2, 12} One also assumes that the intraspinal treatment favors the passage of antibodies from blood into the cerebrospinal fluid, by the following mechanism. Any substance introduced into the spinal canal induces a more or less pronounced meningitis. On the other hand it has been shown by many investigators that congestion of the meninges, of whatever origin, is liable to increase the meningeal permeability toward blood constituents, and substances introduced into the general circulation.^{7, 8} With regard to the induced passage of antibodies from blood into fluid I refer, for illustration, to the following observations. The intraspinal administration of arsenobenzene and horse serum (Dujardin), in patients in whom the Wassermann reaction was negative in the fluid and positive in the blood, was followed by the commonly known meningeal reactions, and the Wassermann test became positive in the fluid. The inference is that the provoked meningitis increased the pas-

sage of luetic antibodies from blood into fluid¹³ Moreover, some data available in the literature are suggestive of a certain relationship between the effects of pyretotherapy and the barrier permeability Experimental studies have shown that in animals infected with various bacteria the permeability increases distinctly (L. Stern)¹⁴ An increased permeability has also been found to be induced by fever in schizophrenic patients (E. Storring)¹⁵ Finally, it has been demonstrated that the meningeal permeability in general paresis, being usually above the normal, experiences a further rise during the malarial treatment (E. Storring, A. Kral) In the light of these observations one may, plausibly, concede that the therapeutic effects in the diseases just mentioned, obtained with fever treatment in general and with the malaria therapy in particular, seem to be somewhat related to the induced functional changes of the barrier permeability

SUMMARY

1 The meningeal permeability, as tested by the distribution of bromide and calcium between blood and cerebrospinal fluid, shows a tendency to an increase in organic psychoses and epilepsy, and to a decrease in schizophrenia

2 The diffusible components of the cerebrospinal fluid should be estimated not as absolute values but as compared to the concentration of these components in the blood

3 The intraspinal treatment appears to be justified reasonably on the ground of the actual knowledge of the function of the barrier between blood and fluid

4 The increased permeability of the barrier, which was found to be induced by malaria therapy and fever treatment in general, may be considered as a contributing factor to the efficacy of these therapeutic methods

The Use of Histamin Hydrochloric Acid As a Test Meal*†

By HENRY H. HAFT, M.D., F.A.C.P., Syracuse, N.Y.

IN recent years there has been a revival of interest and a tendency to evaluate in their proper worth, the various test meals that have been used to determine gastric secretion. Briefly, the Ewald test meal with coffee, tea and toast, seven per cent alcohol, the Schmidt test meal containing meat, bread and vegetables, the raisin and rice evening meal,—all have been given careful scrutiny. The consensus of opinion seems to be that any one test if standardized by one man or in one clinic will give the desired information sought by the investigator.

In functional anacidity, in chronic gastritis with excess mucus production, in heterochylia and true achylia the above mentioned tests are not satisfactory.

In 1923, Ivey, McIlwain and Jarvis applied a one per cent solution of histamin hydrochloric acid to Pavlov pouches in dogs with a resulting prompt and decided secretion of gastric juice. Matheson, in England, and Carnot injected subcutaneously histamin hydrochloric acid and a like effect was shown.

*Read before the Alumni of Syracuse Medical College at the University Hospital May 20, 1931.

†Received for publication, July 13, 1931.

Recently, Gilman and Cowgill of Yale University have proved fairly definitely that histamin acts specifically on the acid-secreting glands and its chief effect seems to be to stimulate production of hydrochloric acid if these glands are functioning. The rapid increase in pepsin following the injection of histamin is not as a result of the direct stimulating effect of the pepsin-secreting glands but rather is due to a generalized flushing of the gastric mucosa and thus the pepsin is increased in a somewhat mechanical fashion. Histamin has no direct stimulating action on the pepsin-secreting glands.

Histamin is a product formed by the putrefactive action of bacteria on the amino-acid histidine. When injected in quantities of one milligram or over it is accompanied by such systemic reactions as fall of blood pressure, increase in pulse rate, flushing of the face, and throbbing sensation in the head with accompanying slight headache. In a dose of one-third of a milligram, this preparation showed absence of these systemic reactions while its effect on gastric secretion remained most pronounced. In this dose the parietal or oxyntic cells of the gastric mucosa are stimulated to secrete hydrochloric acid in a free state and some

of these shock phenomena of histamin are noted

Here, then, is a valuable agent to tell us whether we are dealing with a true or false gastric anacidity. If the parietal cells are functioning, hydrochloric acid will be secreted under the stimulus of this agent. Further, it will be free from the food used as the test meal and it will give more nearly true acid values.

Histamin hydrochloric acid is not a stimulus to the gastric enzyme, pepsin.

For the last year and a half, I have been using histamin hydrochloric acid (Amido-Roche), in all cases coming to the University Hospital, in which we were interested in gastric secretion. This included cases not particularly gastric in their nature, such as chronic eczema, colitis, poisoning due to heavy metals, kidney disturbances and other metabolic diseases. More than 150 such cases have been studied up to date, so that we feel we are able to draw certain conclusions from the test as used in our hands.

Among the contraindications to the test, we have included pregnancy, because of the possible action of histamin in stimulating uterine muscle contraction, and hyperthyroidism, because of a possible effect in producing vasomotor instability.

We have learned that a very safe and harmless dose is one-third to one-fourth milligram. In a few cases one-half milligram of histamin has been used with no untoward effect. We have found that in the smaller dosage it has the same diagnostic value as in the larger dosage.

In most of our cases careful observations were made of the effect on

the pulse rate, blood pressure and other general systemic reactions following its use and much to our surprise and gratification, no unfavorable effects were noted. Usually the blood pressure remained at a fixed level and the pulse rate became even slower 15 minutes to one-half hour after the injection of histamin. In only three cases were flushing of the face and some uncomfortable sensations in the head noted.

Briefly, we performed the test as follows.—On a fasting stomach the duodenal tube is passed into the stomach. This is the usual perforated metal-tip bucket with a thin rubber attached. An estimation is made of the pulse rate and blood pressure and extraction of the gastric content is accomplished. Then histamin hydrochloric acid is injected and every fifteen minutes an extraction is made and labeled, either 1, 2, 3, or 4, depending upon the time of the extraction. With these subsequent extractions, pulse rate and blood pressure were obtained and noted.

In the differentiation between true and false achylia, the test is of inestimable value. In the true achylia, such as we find in pernicious anemia and a few cases of gastric carcinoma, no free acid was found after fractional extraction carried on for a two hour period with fifteen minute intervals. In many cases that had been characterized as true achylia following the common Ewald test meal, free acid was obtained either in the first fifteen minute extraction after the histamin or in the second or third subsequent extraction. In gastric ulcer and duodenal ulcer, the response to

histamin is characterized by a rapid and maintained high acid curve which differs somewhat from the curve described by Rehfuess and others. In chronic gallbladder disease and allied conditions, in which we have been in the habit of obtaining low acid figures and sometimes achylas, in most of our tests, free acid in fairly normal concentration was obtained.

I believe that I am justified in making the following conclusions as to the use of this method:

1 In differentiating between false and true achylia, it is one of the best

methods to use. Further, it is practical and safe.

2 It may stimulate sluggish and dormant gastric secretion.

3 It can be used as a means of determining the amount of hydrochloric acid secretion.

4 It is a powerful stimulant to the parietal or acid-secreting cells of the stomach.

I want to express my appreciation to the members of the Staff for the co-operation in this study and for the privilege of following out this line of investigation, through the courtesy of Dr. E. C. Reifenstein.

San Francisco as a Medical Center

By WM J KERR, M D , F A C P , *San Francisco, California*

Our visitors to the San Francisco session will find a cosmopolitan city, young in point of years but already rich in tradition, modern in external appearance but retaining the charm of earlier days. Marks of the period of Spanish occupation are still evident in its family and place names, in its Mission, which was founded in 1776; and in some of its most cherished customs. Among its population are large racial groups who have brought their culture from many European and Asiatic countries and have retained their individuality to influence the life and thought of this community.

Attracted by the early reports of a warm and equable climate and a wide expanse of rich soil, the early settlers came. These were soon followed by that vast horde, the Argonauts, lured by the cry of "Gold! Gold!", who began one of the greatest pilgrimages the world has ever known. Most of those who came in quest of easy riches from the miner's pan and cradle were disillusioned and soon turned to the soil, the woods and the sea as sources of livelihood. San Francisco became the center of commerce and shipping in the West. With the great influx of adventurers and home-seekers came a number of well-educated men and women and among them a few physicians who had been well trained in the

famous schools on the eastern seaboard and abroad. They transplanted the best scientific and practical medical teaching of the day to a locality where it could flourish unhampered by outworn traditions, and, from the blending arose a new center of medical thought and practice at the Golden Gate.

The rapid growth of San Francisco during the "Gold Rush" days introduced the problem of conserving the health of its people. Many of those who came soon exhausted their resources. In 1850, when the population of San Francisco was less than 100,000, a city hospital became a necessity to care for the indigent sick. Previous to this time such public charges were treated on a contract basis. The care of the destitute sick must have become an acute problem, for, in 1851, the French Mutual Benevolent Society was founded and the German General Benevolent Society was projected. The number of benevolent societies organized by special groups of the citizens increased so that, by 1871, eighty societies classed as benevolent had been formed. The San Francisco Medical Benevolent Society, founded in 1870, later became the California Academy of Medicine. The founders stated that "the objects of this society are for the protection and relief of

deserving physicians and their families who may suffer from sickness and want and to promote kindly professional and social intercourse among themselves and the profession at large" In recent years the Academy of Medicine has limited its objectives. Several meetings have been held each year, and men from all parts of the world have addressed the members and guests upon medical topics of a scientific and practical nature.

By 1870 the San Francisco County Medical Society had become an active force in the professional life of the city. The Society purchased its own home in 1926 (figure 1), where frequent general and section meetings are held. A reference library of approxi-

mately 13,000 volumes is available for its members. Other medical societies have been established until now there is no want for opportunity to attend frequent gatherings each month.

With the growth of San Francisco and the West, the pioneers in medicine recognized the need for some center of medical education near at hand. With such a purpose in mind, a small group under the leadership of Dr. H. H. Toland founded the Toland Medical College in 1864, and delivered the first regular course of medical lectures in the state. Among this small group were Dr. L. C. Lane and Dr. Henry Gibbons, who later joined with others to form the Cooper Medical College under the direction

Fig 1 Home of the San Francisco County Medical Society

Fig 2 Birdseye View of the University of California Medical School Campus, San Francisco.

Fig 3 Life Sciences Building, Berkeley, California

of Doctor Lane. This college later became the Medical Department of Leland Stanford Jr University. The original Toland Medical College, located near the center of the growing city, was reorganized in 1870, and to its faculty came the illustrious John LeConte as Professor of Physiology, who, with his brother, Joseph LeConte, were outstanding figures in the growing University of California (founded in 1868). Dr. R. Beverly Cole joined the faculty as Professor of Obstetrics and Gynecology, and Dean, in 1870, and promoted an affiliation with the University of California which was completed in 1872. Among the notable members of this new faculty were Dr. H. H. Toland, the Drs. H. Gibbons, Senior and Junior, and Dr. A. Barkan. Under the deanship of Dr. R. Beverly Cole, the University of California Medical School raised its standards for admission, and established a four-year curriculum of

instruction. In 1898 the state of California provided funds for new buildings to house the medical school which were erected on Parnassus Heights (figure 2), commanding a superb view of the city and its environs, on land generously donated by the late Adolph Sutro. At the time of the earthquake and fire in 1906, the first two years of instruction were transferred to the University at Berkeley and the medical school building was converted into a hospital and outpatient building for clinical instruction.

Among the notable members of the clinical faculty during this period were Doctor Cole, Dr. T. L. Huntington, Dr. Harry Sherman, Dr. Wm. Watt Kerr, Dr. Douglas W. Montgomery, Dr. Chas. von Hoffman and Dr. Wm. B. Lewitt. The great Jacques Loeb was Professor of Physiology.

In 1912 the faculty was reorganized with Dr. Herbert C. Moffitt as Dean.

Fig 4 University of California Hospital

under whose leadership the medical school continued to grow in importance as a center of medical education. Dr W I Terry became Professor of Surgery and Dr Howard Morrow, Professor of Dermatology. The clinical departments of Obstetrics and Gynecology and Pediatrics were placed on a full-time basis under Dr Frank W Lynch and Dr Wm Palmer Lucas respectively. Many additions were made to the preclinical staff, Dr Frederick P Gay became Professor of Pathology and Bacteriology, Dr Herbert M Evans, Professor of Anatomy, and Dr Walter R Bloor, Professor of Biochemistry. In 1915, the Hahnemann Medical College of the Pacific was taken over, and since

that time elective courses have been offered in Homeopathy. In the past few years the departments of Medicine and Surgery have been developed on a full-time basis. In 1928, Dr Langley Porter became Dean of the Medical School, devoting full time to the post.

In 1931 the state legislature appropriated the sum of \$600,000 for a new clinic building. An increasing number of gifts from friends of the medical school have made it possible to increase the educational and research facilities in all major departments.

In 1917 the University of California Hospital was built on the Parnassus site from funds donated by private

Fig 5 Stanford University Hospital

subscription to the University. Since 1928 the instruction of the last three years has been given in San Francisco. The departments of Anatomy, Physiology and Biochemistry are housed in the new Life Sciences Building (figure 3), completed in 1930, on the University Campus in Berkeley.

Clinical instruction in the University of California Medical School is given at the University of California Hospital (figure 4), in the San Francisco Hospital and at the Children's Hospital, which is an affiliated institution. A fifth or intern year in an approved general hospital is required for graduation, and many hospitals in the state cooperate to provide satisfactory practical experience. By spe-

cial arrangement, the fifth year may be spent in research.

The University of California Hospital is a teaching hospital of 287 beds with a limited number of private rooms for the convenience of members of the staff. The number of students in each class is limited to 60, and men and women of senior standing are admitted on equal terms. Certain courses in chemistry, physics, biology, English and a foreign language are required for admission.

The University of California Medical School has an admirable reference library on the San Francisco campus and a special library for the pre-clinical branches in the Life Sciences Building in Berkeley. A packet service

Fig 6 Lane Medical Library

Fig 7 San Francisco Hospital

to physicians throughout the state has been an important development

The Hooper Foundation for Medical Research is located on Parnassus Heights in a building adjacent to the University of California Medical School and Hospital, with which its work is closely correlated. This institution was established in 1913 through the generosity of Mrs. Hooper in memory of her husband, George Williams Hooper as an institute for medical research. From the beginning, the Hooper Foundation became a center of research activity. Under the direction of Dr. George H. Whipple, important contributions were made in the field of pathological physiology and in tropical medicine. It was in this laboratory that Doctor Whipple and his associates first demonstrated the value of liver in treating experimental anemia. In recent years Dr. E. L. Walker has made contributions to the field of infection and immunity through studies in tuberculosis and leprosy and through studies on chemotherapy. Under the direction of Dr. Karl F. Meyer, studies of benefit to

the state and nation, have been made on botulism, epidemic poliomyelitis, undulant fever, tularemia and poisoning by shellfish. The Pacific Institute of Tropical Medicine, under the direction of Dr. A. C. Reed, is closely affiliated with the Hooper Foundation and the Medical School.

The Stanford Medical School was established in 1908 under an agreement with Dr. Levi Cooper Lane who transferred the properties and equipment of the Cooper Medical College to the Leland Stanford Jr. University. Dr. Elias Samuel Cooper, the uncle of Dr. Lane, had conducted a college under the name of the Medical Department of the University of the Pacific from 1858 to 1864, when it was discontinued. This medical college was reorganized in 1870 and, in 1872, was affiliated with the University College under the name of the Medical College of the Pacific. In 1882 the latter was succeeded by the Cooper Medical College, incorporated by Dr. Levi Cooper Lane. The first building of the medical group was built by Dr. Lane in 1882 on land donated by himself for

Fig 8 Infirmary, Laguna Honda Home

the purpose. An addition to the original building was given by Dr Lane in 1890. Dr Lane built the Lane Hospital in 1894, endowed the Lane Medical Lectureship in 1896, and made provision for a library building. Endowment funds were provided by friends of the College.

The Stanford University Hospital of 130 beds (figure 5) was built in 1917. The Lane Medical Library (figure 6), founded by the Directors

of the Cooper Medical College as directed by the will of Mrs Levi Cooper Lane, contains 73,500 volumes and is one of the most complete medical libraries in America. The building was constructed in 1912. Many friends have contributed funds to provide historical collections in special fields, and among its most generous friends has been Dr. Adolph Barkan. The medical profession of the San Francisco Bay region and throughout the state

of California has been greatly assisted by having such a complete reference library near at hand

The early faculty of the Cooper Medical College included such outstanding teachers as Dr Levi Cooper Lane, Drs H Gibbons, Senior and Junior, and Dr Adolph Barkan. Later Dr Hans Zinsser became Professor of Bacteriology and Immunity. For a number of years Dr Ray Lyman Wilbur was Professor of Medicine and Dean before assuming the presidency of the University. Dr Stanley Stillman, Dr Emmet Rixford

and Dr Adolph Barkan held important faculty positions. Dr Albion Walter Hewlett, who was Professor of Medicine until his untimely death, was an inspiring teacher and investigator. Dr Wm Ophuls who came to San Francisco as Professor of Pathology and Bacteriology in 1898, has held an honored position in the scientific life of the school and community, and in recent years has been Dean of the medical school. Dr Thomas Addis has made valuable contributions to the field of pathological physiology.

Instruction in Anatomy, Bacteriolo-

Fig 10 Franklin Hospital

gy, Biochemistry, Histology, Neurology and Physiology is given on the campus at Stanford University. The entering class is limited to 50 students who have completed three full years of academic studies, with required courses in chemistry, physics, biology and English, and who have a reading knowledge of French or German.

The work of approximately the last three years is offered at the Stanford University School of Medicine in San Francisco. Clinical facilities are available for 50 students at the Lane Hospital with approximately 150 teaching beds and on the Stanford Service at the San Francisco Hospital. A large outpatient department is located adjacent to the Lane and Stanford Hospitals. The Hydrotherapeutic and X-Ray Departments and the Clinical Laboratories are located in the Stanford University Hospital, which has a capacity of 130 beds. A fifth or intern year in an accredited hospital or in special laboratory work is required of all students before graduation.

In addition to the two university hospitals there are many others which, from the early days of San Francisco,

have developed as expressions of the desire for service which characterizes the public and our profession alike. The total number of available hospital beds in San Francisco is beyond the needs of its people. In the Marine and Letterman General Hospitals there are many beds for special government groups, and in the Southern Pacific Hospital for employees who are sent from other states in the West. Many patients from outside the city also seek professional care in the city.

It is beyond the scope of this paper to discuss the hospitals and medical facilities of the entire region. The counties bordering on the San Francisco Bay are, however, closely united in upholding the best traditions of medicine. In Alameda County there are many outstanding hospitals, among which may be mentioned the Highland Hospital, operated as a general hospital and modern in every respect, and the Ernest V. Cowell Memorial Hospital which serves as the health center for students of the University of California. San Mateo County, lying south of San Francisco, on the peninsula, boasts one of the finest

Fig 11 St. Mary's Hospital

Fig 12 St Luke's Hospital

hospitals of moderate size in America. It was built and endowed by the late Mrs. Whitelaw Reid as an outgrowth of interest in Red Cross work during the World War. The new Palo Alto Hospital has just been completed in Palo Alto to serve the needs of the community and under a special arrangement is available for students of Stanford University. This hospital is on university property and is under the supervision of the Director of the Lane and Stanford Hospitals.

The San Francisco Hospital (figure 7), one of the most modern general or municipal hospitals in America, was begun in 1909 and the main group of buildings was completed in 1915. The total cost of construction and equipment was approximately \$3,500,000. Accommodation was provided for 512 patients. With additions, since 1915 and including new wards, the capacity has been increased to 1280 beds. There are special departments for

tuberculosis and contagious diseases. Land has recently been purchased, upon which will be constructed a new Psychopathic Institute of 149 beds and a Cancer Institute of 198 beds. The hospital is under the administrative control of the municipal Department of Health and is supported by taxation. From the early days in San Francisco the city has made ample provision to care for its sick, and this modern group is but the last of a long list of structures built for the purpose. The professional services of San Francisco Hospital are divided equally between the clinical staffs of the two university medical schools. The spirit of cooperation between the municipal authorities and the medical schools has been most cordial, and the highest type of instruction has been given to students under this arrangement.

The Laguna Honda Home (figure 8) is in part a hospital for chronic

diseases and in part an institution for the indigent and infirm of the city and county of San Francisco. There are 500 beds for patients, and living accommodations for 2000 of the indigent and infirm. The staffs of the two medical schools render the professional service, and patients are available for instruction in the chronic disorders and diseases of the aged. The city of San Francisco also maintains an official emergency service with stations in several sections of the city. A pre-

ventorium for tuberculosis is maintained in Redwood City approximately 25 miles south of San Francisco.

The San Francisco Health Department is under the direction of a full-time and efficient administrator who is concerned with the promotion of general health and the control of communicable diseases. The city ranks high among American cities in its health rating.

The French Hospital (figure 9) is owned and operated by a French Mu-

Fig 13 Entrance to Main Building, Children's Hospital

tual Benevolent Society which had its origin in 1851, when the need arose to provide some care for the poor and destitute French who came to California in quest of gold. At present the Society has a membership of 9,000 restricted to French people or people of French extraction and those speaking French, and strives to give the best care and treatment to its members. The Society owns and operates the French Hospital of 220 beds, which is modern and complete in all respects. The professional staff includes many outstanding physicians and surgeons of French extraction.

The present Franklin Hospital, formerly the German Hospital, (figure 10) was completed in 1908 and is the third hospital building owned by the German Benevolent Society. The Society was founded in 1854, and the first hospital to provide care for its members was built in 1857. The present modern and well-equipped hos-

pital occupies a sheltered site near the center of the city.

The first Marine Hospital in San Francisco was opened in 1853. Previous to this time seamen were given medical relief by contract surgeons. For two years previous to 1853, seamen were treated on board a revenue bark stationed off Fort Mason. A second Marine Hospital was constructed, in 1874, on the site of the present hospital and was in continuous operation until 1931. The new Marine Hospital has 400 beds and is complete in every detail. Outpatient departments are conducted at the hospital and in the Appraisers' Building near the water front. This hospital provides care and treatment for sick and disabled seamen of the American Merchant Marine. Service is also rendered to employees of the Government injured in line of duty and to beneficiaries of the Employees' Compensation Commission, to officers and en-

Fig. 14 St. Joseph's Hospital

diseases and in part an institution for the indigent and infirm of the city and county of San Francisco. There are 500 beds for patients; and living accommodations for 2000 of the indigent and infirm. The staffs of the two medical schools render the professional service, and patients are available for instruction in the chronic disorders and diseases of the aged. The city of San Francisco also maintains an official emergency service with stations in several sections of the city. A pre-

ventorium for tuberculosis is maintained in Redwood City approximately 25 miles south of San Francisco.

The San Francisco Health Department is under the direction of a full-time and efficient administrator who is concerned with the promotion of general health and the control of communicable diseases. The city ranks high among American cities in its health rating.

The French Hospital (figure 9) is owned and operated by a French Mu-

Fig 13 Entrance to Main Building, Children's Hospital

tual Benevolent Society which had its origin in 1851, when the need arose to provide some care for the poor and destitute French who came to California in quest of gold. At present the Society has a membership of 9,000 restricted to French people or people of French extraction and those speaking French, and strives to give the best care and treatment to its members. The Society owns and operates the French Hospital of 220 beds, which is modern and complete in all respects. The professional staff includes many outstanding physicians and surgeons of French extraction.

The present Franklin Hospital, formerly the German Hospital, (figure 10) was completed in 1908 and is the third hospital building owned by the German Benevolent Society. The Society was founded in 1854, and the first hospital to provide care for its members was built in 1857. The present modern and well-equipped hos-

pital occupies a sheltered site near the center of the city.

The first Marine Hospital in San Francisco was opened in 1853. Previous to this time seamen were given medical relief by contract surgeons. For two years previous to 1853, seamen were treated on board a revenue bark stationed off Fort Mason. A second Marine Hospital was constructed, in 1874, on the site of the present hospital and was in continuous operation until 1931. The new Marine Hospital has 400 beds and is complete in every detail. Outpatient departments are conducted at the hospital and in the Appraisers' Building near the water front. This hospital provides care and treatment for sick and disabled seamen of the American Merchant Marine. Service is also rendered to employees of the Government injured in line of duty and to beneficiaries of the Employees' Compensation Commission, to officers and en-

Fig. 14 St. Joseph's Hospital

listed men of the U S Coast Guard, Coast and Geodetic Survey, Light-house Service, and to seamen of the Bureau of Fisheries and of Army transports. Marine Hospitals also admit sick immigrants for treatment.

The St. Mary's Hospital (figure 11), the oldest Catholic Hospital in California, was opened in 1857 by the Sisters of Mercy. A new and larger hospital was constructed on Rincon Hill in 1861. This building, with additions, was destroyed by the earthquake and fire in 1906, but at once a new site was selected near Golden Gate Park and within five years a modern hospital was constructed. Additions were made in 1926, bringing the capacity to 325 beds. This hospital has held an important place in the community.

The St. Luke's Hospital (figure 12) was established in 1871, by the Rev. Thomas Woodley Brotherton,

M.D., D.D., who practiced medicine in the mining section of the state until 1855 and who, in 1860, was ordained a Deacon in the Episcopal Church. The original building with additions was destroyed in 1906. In 1911, the present buildings were erected by Lydia Paige Monteagle, Ogden Mills and Elizabeth Mills Reid, in memory of Calvin Paige and Darius Ogden Mills. Additions, in 1924, increased the capacity to 200 beds. This hospital aims to meet the demand for so-called "middle-class" hospital care by offering moderate rates to those who pay full costs, and by supplementing the income from those who can pay but part of the costs, through the agency of endowment funds.

The Hospital for Children and Training School for Nurses, commonly known as the Children's Hospital (figure 13) was founded in 1875. Although primarily a benevolent institu-

Fig 15 Mount Zion Hospital

tion, both private and service patients are accommodated. The present capacity is 275 beds, with an outpatient department. One wing is devoted entirely to the care of communicable diseases, and another wing provides excellent maternity care. Women patients with general medical and surgical conditions are cared for in the main building and there are special wards for children.

The St. Joseph's Hospital (figure 14), operated by the Franciscan Sisters of the Sacred Heart, was erected in 1892. Additions were made in 1900 and in 1906. Since 1906 this institution has been known as St. Joseph's Home and Hospital, providing service to the incurable and admitting to the hospital medical and surgical patients.

In 1928, a new modern hospital building was completed on the site, and is operated as a religious and charitable institution.

The Mount Zion Hospital (figure 15) is a general hospital of 150 beds operated by the Federated Jewish Charities of San Francisco. The first hospital was opened in 1897 but was so inadequate that two years later a larger structure was provided which served until 1912, when a modern hospital building was constructed. A large number of beds are reserved for charity cases. In 1931 special clinical and research laboratories were constructed.

The Letterman General Hospital (figure 16) is one of the great Army hospitals in the country. It had its

Fig. 16 Letterman General Hospital United States Presidio

origin in 1898 during the war with Spain when the Eighth Army Corps was under mobilization for the First Philippine Expedition. Division field hospitals were found inadequate, and a temporary general field hospital was accommodated in the brick barracks at the Presidio of San Francisco. Later during the same year the War Department established the United States Army General Hospital, although permanent quarters were not begun until 1899. In 1900 a permanent hospital was completed to accommodate 380 patients. In 1911, the War Department designated the new hospital the Letterman General Hospital in honor of the late Major Jonathan Letterman, Surgeon, U S Army, who effected the organization of the medical department of the Army of the Potomac during the Civil War. In 1917, the hospital was rapidly ex-

panded by the construction of some 27 temporary buildings to meet the World War conditions. Today it comprises 59 permanent and 26 temporary buildings with a capacity of 965 beds. In addition to serving the military posts of the entire Pacific Coast and of our foreign possessions, accommodations are provided for about 400 beneficiaries of the Veterans' Bureau. The professional service rendered in this hospital has always been of high order.

The St Francis Hospital (figure 17), organized in 1904, is a general hospital of 325 beds owned and operated by physicians. A number of beds are available for free and part-pay patients.

Mary's Help Hospital (figure 18), conducted by the Sisters of Charity of St Vincent de Paul, was under construction when the great calamity be-

Fig 17 St Francis Hospital

fell San Francisco in 1906, and the building was entirely destroyed. A new structure was completed in 1912 with 160 beds for all types of patients except those suffering from mental and communicable diseases. A large outpatient department is maintained. The principal aim is to provide efficient and adequate care for the sick poor and for people of moderate means.

The Southern Pacific Hospital was built in 1909 by the Southern Pacific Railroad Company especially to serve the employees of this railway system. The hospital serves as a center for a widespread and coordinated plan to protect the health of its employees and to restore them to usefulness. A large

addition was completed in 1930 which increased the capacity to 500 beds.

The Shriners Hospital for Crippled Children is one of a chain of such hospitals founded and maintained by the Ancient Arabic Order, Nobles of the Mystic Shrine, and located in many cities in America. The San Francisco Shriners Hospital was founded in 1923, with 60 beds, and is devoted to the correction of remedial defects among children under fourteen years of age whose parents or guardians are financially unable to provide the necessary treatment. Children are able to continue their school work while undergoing treatment, through the cooperation of the Board of Education.

Fig. 18 Mary's Help Hospital

Editorial

MEDICINE TO-DAY AND TO-MORROW

Old General Depression lays his hand heavily on our profession and the average doctor somewhat suddenly awakens to the fact that all is not well and that "something must be done about it"

For some time he has sensed forces at work which, in their operations, were detrimental to him. In a more or less academic way he has read in lay magazines, articles which indicated an unrest on the part of the public, criticisms of the doctor, the hospitals, protests against the cost of medical care. In professional magazines he has read articles by those who are looked upon as leaders of his profession, expressing a concern about the situation, but except where encroachment here and there has hit his income directly, he has gone on his busy way unconcerned, or at least not sufficiently concerned to do more than scold about an irritating situation.

Certainly he has not been truly conscious of the strong social movement which is now in the air. In his address to the College of Surgeons, Dr. Angell speaks of the new philosophy "which conceives the social order as under binding obligation to give its members wholesome conditions of life which conceives human life as indisputably superior to money or physical property in any form." We must listen attentively to his conclusions

that "in the long run, by hook or by crook, society will demand competent medical and nursing service, adequate in amount to meet the needs of everyone. If it cannot secure these as the result of measures voluntarily devised and perfected by the profession and its interested friends, it will look to other agencies, and notably to the Government, to produce the desired results."

The entire world is in a state of flux. In finance, in religion, in constitutional law, as well as in medicine, we seem to be in an irresistible stream, the course of which is uncharted and the end not in sight. It is a period of maladjustment, and a period in which maladjustments long existent are being emphasized. Re-adjustments become a necessity and with these re-adjustments comes the opportunity for the correction of maladjustments, many of them of long standing and of very gradual growth.

• It is a time for those who, by reason of official position or by reason of unusual ability, are the leaders of our profession to put their minds together and help us to chart our course. It is not the time for reactionary impulsive action, impractical experiments, or challenging attitudes. We must be on guard against impractical panaceas which come either from within or from without the profession, and hope that no such panaceas will obtain legislative approval.

It is not unlikely that there is to be a distinct change in the character and

type of medical practice in the next generation. A variety of social movements affecting medicine are under way, and their development is not to be stopped. State medicine is edging its way in and is not to be entirely kept out. That concessions must be made, compromises accepted, must be recognized by the rank and file of the profession. It will be the obligation of our leaders to guide, so far as they may, these movements, and to advise us when such concessions are necessary and compromises essential.

The action of the California Medical Society with its proposed public relations office with paid secretary and corps of assistants, and the Michigan plan for a survey of medical activities within the state, indicate that medicine is not unmindful of its obligations.

If state medicine is not to come if institutional practice is not to be more common than it is now, if charitable clinics and governmental medical agencies are not to continue their progressing encroachments, then the rank and file must not be content with this shifting of responsibility to their leaders, but must do their part as individuals. Open warfare against all clinics, good and bad, and social movements of various sorts whose objective is the care of the sick, will not only be futile, but is certain to be detrimental to the entire professional body. Charitable clinics, however much they permit abuses, however much they may impinge on the individual's practice, have a legitimate objective and were started with the best of intentions. Over-enthusiasm sincere enough, and over-ambition on the

part of a paid secretary, are usually responsible for the over-activity and the associated abuses. The individual doctor may do much through personal contact with his acquaintances and patients who are members of lay boards. Properly approached they cannot fail to recognize that the doctor has an interest at least equal to their own in community welfare. It might be well to remind them that these clinics are dependent on the doctor for their very existence, and that the public is today asking the doctor to carry a disproportionate philanthropic load as compared with other individuals in the community.

The obligation rests upon medicine, first, to do its part in making the doctor more competent to fulfill his obligation to his patient and to the community, and second, to direct educational presentations to the public, to the end that the public shall more properly evaluate the doctor's services, and realize the extent of its dependence upon him for good health and happiness. We must have our finger in the pie. Through our representatives we must be in a position to guide where we may this evolutionary process. Society and the profession will equally benefit if this evolution proceeds sanely and along such lines as will permit the medical profession to maintain its ideals and continue to endow mankind with discoveries and with the application of discoveries, such as have, in the past, brought so much of health and happiness into the world. The way must be found for these things to be maintained with the doctor leading a truly independent life assured of sufficient income to make it

possible for him to give the best that medicine has to offer to his patients, and to make life for him reasonably happy and satisfactory. The way will come if the profession will only maintain a unified front. We have ever shown a lack of real cohesiveness. Individualists by training and temperament, we have never been willing to play the game as a group. As this

new social order comes into being, adjustments will be difficult, and some sacrifices will be necessary and imperative. This must be recognized and accepted.

(Contributed editorial by BURTON R. CORBUS, B.S., M.D., F.A.C.P., Chairman of the Executive Committee and of the Council of the Michigan State Medical Society.)

Climate as a Potential Factor in the Etiology of Exophthalmic Goiter and the Other Metabolic Diseases. By C. A. MILLS, M.D. *Endocrinology*, 1932, xvi, 53-63.)

The geographical distribution of exophthalmic goiter, when correlated with possible specific factors, may yield information of value in respect to the etiology of this disease. This is a field of investigation which is far from being exhausted. A simultaneous study of other diseases of endocrine dysfunction and of metabolic exhaustion, such as diabetes and pernicious anemia, should be of value as a control. Using mortality statistics as a basis, and calculating the deaths from each disease as a percentage of the total number of deaths in given areas, distribution maps have been prepared for North America, and likewise climate maps of the continent with special reference to storm areas, storm frequencies, and day-to-day variability of the temperature. From such maps it is observed that the three diseases named are most severe in two areas, one centering around the Great Lakes region, and the other covering the Pacific Northwest from San Francisco northward. The death rates in these regions for these diseases are very much higher than they are in the southern states or in the far north. The highest rates are found in the Great Lakes region where the total death rate from all causes is low and the death rate from the various acute infectious diseases no higher than elsewhere. Climate maps show the Great Lakes area to possess the highest

storm frequency to be seen anywhere in the northern hemisphere, and to have great temperature variability as compared to the South. The Pacific coast, from San Francisco northward, shows a low variability of temperature and few storms, but remains at all times of the year within the limits of the optimum for human activity. It thus appears that the maximum metabolic breakdown occurs in the two areas where climatic stimulation of humanity is the greatest. It would seem that excessive stimulation may be the basic factor which brings a small number of people too near the limits of their metabolic capacity.

The Incidence and Situation of Myocardial Infarction in One Thousand Consecutive Postmortem Examinations. By ARLIE R. BARNES, M.D., and RALPH G. BALL, M.D. (*Am. Jr. Med. Sc.*, 1932, clxxxiii, 215-225.)

Myocardial infarction was recognized grossly in the hearts of 49 subjects in a series of 1000 unselected consecutive postmortem examinations. Only two examples were found in the hearts of 315 patients less than 40 years of age. When this group is excluded, the gross incidence of 4.9 per cent is increased to 6.86 per cent. Forty of the subjects with myocardial infarction were men. One had had a definite history of syphilis, a second, a questionable history of syphilis, and a third had had a positive Wassermann reaction upon the blood and spinal fluid and definite neurological evidence

of syphilis of the central nervous system. Five patients had given histories of angina pectoris, or dyspnea, or both, preceding the signs and symptoms indicative of the first coronary occlusion. In 24 there had been a definite history of coronary occlusion. Of 12 in whose hearts multiple myocardial infarctions were found, 9 had given histories of a second coronary occlusion. As to location, myocardial infarction was observed in the posterior basal portion of the left ventricle in 24 instances and in the apex and anterior portion of the left ventricle in 28 instances. Combining the cases in which actual occlusion of an artery was demonstrated with those in which the artery concerned was identified by dissection although the point of occlusion was not proved, it was found that the anterior descending branch of the left coronary artery was responsible for gross myocardial infarction in 28 instances, the circumflex branch, in 17, and the right coronary artery, in 20. More careful pathologic study of the posterior basal portion of the left ventricle is urged in order that infarctions in that region may not be overlooked. The designation of the left coronary artery as "the artery of coronary occlusion" is no longer justifiable.

A Clinical Study of Etiology of Gastric and Esophageal Carcinoma By LLOYD F CRAVER, M.D. (Am Jr Cancer, 1932, xvi, 68-102)

A group of 36 patients having cancer of the stomach and another group of 18 having cancer of the esophagus provide the clinical material used in this study. In addition to the family history, detailed inquiry was made in regard to 16 points in the previous life of each patient. Ten of these points were concerned with food factors, including the use of alcohol, water, size of meals, rapidity of eating, heat of ingesta, coarseness of foods, amount of seasoning, irregularity of meals, dental disease and presence or absence of teeth. The remaining factors were drug consumption, particularly as concerned cathartics, history of other gastro-intestinal diseases, sinusitis and tonsillitis, and evidence of arteriosclerosis. These factors were as-

signed graded values for each patient, and when the two groups were compared definite discrepancies were found between the factors receiving the higher scores in cases of carcinoma of the stomach and those receiving the higher scores in cases of carcinoma of the esophagus. For cancer of the stomach, the following factors stood in the higher ranks: poor teeth, lack of teeth, other gastro-intestinal diseases, heat of ingested food and drink, irregularity of meals, lack of water, seasoning, drugs (cathartics), rapid eating, tobacco, and alcohol, in the order named. For cancer of the esophagus, the following factors attained the higher scores: tobacco, alcohol, lack of water, poor teeth, lack of teeth, and drugs (cathartics). While the groups concerned are probably too small to permit the drawing of definite conclusions, the method is one which promises data of great value in respect to the etiology of these forms of carcinoma. It is pointed out that it was primarily by this method that the extrinsic factors in the causation of industrial cancers of the skin and bladder were discovered.

Reasons for the Use of Carbon Dioxide with Oxygen in the Treatment of Pneumonia By YANDELL HENDERSON, Ph.D. (New England Jour of Med, 1932, ccvi, 151-155)

The tent method of administering inhalation treatment to pneumonia patients seems to be establishing itself as the best under most circumstances. Intranasal insufflation is generally much less effective in overcoming cyanosis and involves considerable waste of gas. Feverish patients, already experiencing a feeling of suffocation, object to a mask held over the face. Oxygen chambers are expensive and also involve a serious fire hazard. In this article a tent is illustrated which is designed particularly for the administration of a mixture of oxygen and carbon dioxide, now generally termed "carbogen." The use of carbon dioxide and oxygen in combination in the inhalation treatment of pneumonia affords the following advantages:

"(1) Deeper breathing is induced which prevents the development of occlusion and

tends to open parts of the lungs already occluded

(2) Under inhalation of carbon dioxide, morphine or other narcotic drugs may be used more freely to counteract excitement and restlessness. The stimulus to respiration afforded by carbon dioxide tends to counteract the depression of breathing which such drugs otherwise induce.

"(3) Carbon dioxide in solution becomes carbonic acid and tends to exert a bactericidal action upon the pneumococcus and a resolving action upon the pneumonic exudate. These effects are best obtained when inhalation of carbon dioxide is combined with administration of morphine or other narcotic and respiratory depressant drugs. While carbon dioxide tends to lower the pH of the blood and of the pneumonic exudate, it does not decrease the blood alkali or tend to induce an acidosis, but rather the contrary."

Nodular Hyperplasia of Adrenal Medulla in Hypertension. By M. A. GOLDZIEHER, M.D. (Endocrinology, 1932, xvi, 20-28)

The list of cases of pheochromocytoma tumors occurring in patients with hypertension has been increased to include at least 42 examples. In several instances the

diagnosis has been made during life, and surgical removal of the tumor with relief of symptoms has been accomplished. This seems to argue rather strongly for the conception that an excessive amount of chromaffin tissue, such as is represented by these tumors, is capable of producing symptoms of hypertension, to be followed by lesions of the arteries. The evidences that the adrenals may play a part in the pathogenesis of hypertension and arteriosclerosis have been grouped under four heads: increased adrenalin content of the glands, hypertrophy of the musculature of the adrenal veins, morphological changes in the adrenal cortex, and diffuse hyperplasia of the adrenal medulla. In the present paper a nodular hyperplasia of the chromaffin tissue is described. In each of four cases, one or more nodular formations were found in the adrenal medulla, associated with a diffuse hyperplasia. Two of these cases, clinically, gave evidence of high blood pressure. As to the other two, the author believes that sclerosis of the aorta and of peripheral arteries was sufficient evidence that hypertension had existed previously. Further anatomical studies will be needed to determine the extent to which the changes described in this paper are found in association with hypertension.

Reviews

Asthma and Hay Fever in Theory and Practice Part I Hypersensitiveness, Anaphylaxis, Allergy. By ARTHUR F. COCA, M.D., Professor of Immunology, Cornell University Medical College, Clinical Professor in Medicine-elect, New York Post-Graduate Medical School. Editor of The Journal of Immunology. *Part II Asthma.* By MATTHEW WALZER, M.D., Instructor in Applied Immunology, Cornell University Medical College, Deputy Attending Physician, Clinic of Applied Immunology, New York Hospital, Chief of Allergy Clinic, Jewish Hospital of Brooklyn. *Part III Hay Fever.* By AUGUST A. THOMMEN, M.D., Lecturer in Medicine, University and Bellevue Hos-

pital Medical College, Director of the Allergy Clinic, Medical College Dispensary, New York University. xxiv + 851 pages, 95 figures, numerous tables and charts. Charles C. Thomas, Springfield, Illinois, 1931. Price, \$8.50.

The writer reviews this book with enthusiasm. It gives a very thorough, studious and scholarly review of the entire field which its title and sub-titles indicate. So complete and comprehensive is it, that a review dealing with single phases of the subject seems inappropriate. Whether etiology, pathology, diagnosis and testing, microbotany or treatment, happens to be the reader's quest, he will find here a critical monographic presentation of the de-

sired subject matter. Certain minor points will be questioned by other workers in this field. In fact, the three authors acknowledge the inevitable lack of complete accord which exists among themselves. This is in itself a pledge of honest, scientific workmanship. The use of a compact type face, with much quoted matter in a smaller type than the body of the text, has made it possible to put an unusual amount of information between one pair of book covers. Extensive bibliographic lists are provided, with 400 titles under Part I, 1077 under Part II, and 628 for Part III. The index is conveniently divided into two parts, one is a general index and the other a special list of atopens and excitants. This book should be in the intimate library of everyone working in the field of allergic disease. Its value will be appreciated by the clinician as well as by the investigator in the laboratory.

Heart Disease. By PAUL DUDLEY WHITE, M.D., F.A.C.P., xvii + 931 pages, 119 illustrations, 9 tables. The Macmillan Co., New York City, 1931. Price, \$12.00.

This volume, one of the Macmillan Medical Monographs, is an exhaustive, logical and competent treatment of the subject, and might well have been entitled "Cardiovascular Disease" since the author, realizing the inseparability of diseases of the heart proper from those of the blood vessels, has wisely treated of both, although the emphasis is placed upon affections of the heart itself. Divided into four major parts, the content of the book is available for either reference or textual use. The material is carefully outlined and lucidly presented so that a minimum of time is required to find the discussion of any given topic. The first major division comprises a manual for the conduct of the clinical investigation, including suggestions for record forms, methods of history taking and general procedures of bedside and laboratory examination with special reference to the various maneuvers useful in cardiological study. Separate chapters are devoted to cardiovascular roentgenology and electrocardiography. Numerous illustrations of excellent quality add to the clarity of the text. Part II is a systematic treat-

ment of the etiological factors of heart disease. Here, necessarily, the arrangement and attack are somewhat arbitrary, but the reader will readily find that his fields of special interest receive just consideration although it may be that the scheme of classification is unlike that to which he has been accustomed.

Morphological abnormalities of the heart are considered in Part III. This is the least satisfactory section of the book. In a text of this size, one might expect this phase of the subject to be treated in a much more comprehensive manner. This lack is especially evident in the discussion of the pathology of cardiac syphilis. The author has evidently labored under a sense of restraint lest the section on morphological pathology become unduly large. Fuller descriptive treatment and the addition of more illustrations in this part would have been of advantage to many readers. Part IV is devoted to the consideration of disorders of the heart which are primarily functional and which are not necessarily conditioned upon demonstrable structural abnormality. Inevitably, Parts III and IV overlap somewhat but the division of material in this manner enhances the orderliness of the presentation and also facilitates the use of the book for reference purposes. The prognosis and treatment of the various disorders are to be found under the specific topics and no especial section is devoted to therapy. This procedure tends to avoid repetition and is conducive to compactness of arrangement. An extensive bibliography, requiring nearly 200 pages, is appended, and to those engaged in cardiological work, this portion alone is worth the cost of the volume. The space occupied by this section might have been much reduced by using a smaller type face, without impairing its value. The reviewer would have gladly accepted this space economy in the interest of a fuller treatment in Part III. The Index is unusually well planned and has proven adequate when put to repeated tests.

Simplified Diabetic Management. By JOSEPH T. BEARDWOOD, JR., A.B., M.D., F.A.C.P., Chief of Diabetic Clinic and Associate Visiting Physician, Presbyterian Hospital.

in Philadelphia; Physician in Chief to the Department of Metabolic Diseases, Abington Memorial Hospital, Associate in Cardiology, Graduate School of Medicine, University of Pennsylvania, and HERBERT T KELLY, M D, A A C P., Associate in Diabetic Clinic, Presbyterian Hospital in Philadelphia, Associate in Cardiology, Graduate School of Medicine, University of Pennsylvania, and in The Philadelphia General Hospital, Diets prepared with the collaboration of Elsie M Watt, A B, formerly Dietician, Diabetic Clinic, Presbyterian Hospital in Philadelphia 191 pages, illustrations, folding chart J P Lippincott Company, Philadelphia Price, \$1.50

This book is arranged in three chapters and is primarily for the patient. In the first there is a simple statement of the nature of diabetes, of the dietetics of this disease and of the unit method of planning the menu of the diabetic. Here also is found information in regard to insulin and its use. The second chapter is written with the needs and interests of the more intelligent "well-trained" diabetic in mind, while in the third are grouped the various tables of food values, recipes and suggested menus. For the more intelligent patient this book will be of interest and value. Others are apt to be discouraged by the apparent complexity of the "Diet Prescription Chart" and its application. A few minutes study will show that this complexity is more apparent than real.

The Modern Therapeutics of Internal Diseases. An introduction to Medical Practice. By A P CAMADIAS, O B E, M D (Durh and Paris), M R C P (London), formerly Chief of the Therapeutic Clinic of the Faculty of Medicine of the University of Paris, formerly Senior Physician and Lecturer for Internal Diseases, Evangelismos Hospital, Athens xi + 147

pages William Wood and Company, New York, 1931 Price, \$3.75 net

The presentation of a philosophy of therapeutics is the aim of this book, thus the purchaser who expects specific advice for the therapy of disease may feel that he has been deceived by the title. The thesis that there are no diseases, but only diseased individuals, is stressed throughout. Certainly, there is nothing new in this conception but there is much to be gained by keeping it in mind. The style is heavy, somewhat involved, and reminiscent of a preceding century. In the few instances in which the author leaves the realm of the abstract some rather unusual pronouncements appear. On page 118, it is stated that glandular organo-therapeutical preparations are of the greatest importance in the treatment of *tetanus*. Doubtless *tetany* was intended. Colloidal gold is said to provoke principally the production of antityphoid antibodies. Aside from its emphasis upon the individual as a whole and the importance of constitution, this book has but little to recommend it to the American physician.

Die Verkalkung der Gewebe. By Dr GEORGE MEYER ZU HORSTE 74 pages, 10 illustrations S Karger, Karlstrasse 59, Berlin, 1932 Price, 7 M

This monograph is based upon an experimental investigation of the factors influencing the deposition of lime salts in tissue. Rachitic epiphyseal sections from young rats which had been on McCollum diet No 3143 were immersed in Shipley's solution, with such chemical-physical alterations in the solution as were under investigation. The deposition of lime salts in the test object and the changes in the medium were studied quantitatively by appropriate methods. This work will be of considerable importance to those engaged in research in the fields of physiological and pathological calcification.

College News Notes

AN URGENT RESPONSIBILITY OF FELLOWS AND MASTERS

Candidates for membership, either Associateship or Fellowship, in the American College of Physicians, must be proposed, seconded and endorsed by Fellows or Masters of the College in a manner prescribed by the By-Laws. When such proposals are filed in the office of the Executive Secretary, a card of notification of said proposal is sent to every Fellow and Master residing in the district from which the candidate comes. This notification card requests each Fellow or Master to file immediately in the office of the Executive Secretary information for or against the election of said candidate. Communications are treated as strictly confidential, being referred no further than to the Committee on Credentials.

These announcement and inquiry cards are of great assistance to the Committee on Credentials when reviewing the candidates for election. In most localities, Fellows and Masters carefully fulfill their responsibility by furnishing information about each candidate but many times these cards are not promptly returned, or not returned at all. Some apparently have assumed that if they do not know the candidate, or if they do not favor his election, they should not return the card at all. The Committee intends that all cards be returned whether the candidate is known or not. It is at least of assistance to ascertain how widely the candidate is known among the Fellows and Masters of the College in his district or state.

The Committee on Credentials expends much time and honest effort in determining the qualifications of candidates for election. Members will assist tremendously by promptly returning all inquiry cards after noting thereon their unbiased opinion of the candidate's qualifications for election.

NOMINATIONS FOR ELECTIVE OFFICERS

1932-1933

The Nominating Committee herewith transmits the following nominations for elective officers of the American College of Physicians for the year 1932-1933

President-Elect—George Morris Piersol, Philadelphia, Pa

1st Vice President—Maurice C Pincoffs, Baltimore, Md

2nd Vice President—Charles G Jennings, Detroit, Mich

3rd Vice President—Noble Wiley Jones, Portland Ore

Respectfully submitted

Alfred Stengel, Chairman

February 19 1932

ABSTRACT OF MINUTES MEETING OF THE BOARD OF REGENTS

Chicago, Ill ,

December 20, 1931

The Board of Regents of the American College of Physicians was called to order in Room 325, Drake Hotel, Chicago, Illinois, at 9 50 A M by the President, Dr S Marx White, Minneapolis, Minnesota

The following were present Drs S Marx White, Francis M Pottenger, Charles G Jennings, Clement R Jones, George Morris Piersol, David P Barr, James B Her- rick, Maurice C Pincoffs, Walter L Bierring, George E Brown, John H Musser, O H Perry Pepper, James H Means, James Alex Miller, Sydney R Miller, W Blair Stewart, Carl V Weller (Editor of the Annals of Internal Medicine), and Mr E R Loveland, Executive Secretary

Extracted minutes of the previous meeting were read by the Executive Secretary and approved

The Executive Secretary reported the receipt of communications from Drs J A Lichty, A R Elliott, N W Jones, J R Arneill, J C Meakins and James S McLester expressing regret at inability to be in attendance at the meeting

The following deaths since the last Regents' meeting were reported by the Executive Secretary

Fellows

Leonard Napoleon Boston	Philadelphia, Pa	July 4, 1931
Lawrence Evans Chapman	Galveston, Texas	October 21, 1931
Edward Tyler Edgerly	Ottumwa, Iowa	November 13, 1931
Thompson Frazer	Newark, N J	October 9, 1931
Harry M Hall	Wheeling, W Va	June 5, 1931
Horace Howard Jenks	Philadelphia, Pa	July 6, 1931
Bradford Churchill Loveland	Syracuse, N Y	June 25, 1931
John F W Meagher	Brooklyn, N Y	August 25, 1931
Leonard Milton Murray	Toronto, Ont	August 8, 1931
James Percy Schureman	New Brunswick, N J	May 6, 1931
Arthur Clifford Selmon	Battle Creek, Mich	May 16, 1931
William Stephens Shields	Denver, Colo	August 6, 1931
Elmore Callaway Thrash	Atlanta, Ga	June 22, 1931
Henry Lyle Winter	Newburgh, N Y	July 29, 1931

Associates

Robert Gibbs Douglas	Shreveport, La	July 23, 1931
Theodore Leacraft Hein	New York, N Y	September 25, 1931
William A Monroe	Sanford, N C	1927
Edward Peter Schatzman	Pittsburgh, Pa	July 27, 1931
Joseph Witham Young	Toledo, Ohio	July 14, 1931

The following resignations were accepted

Dr Frank M Conlin (Fellow), Omaha, Nebr

Dr Henry D Jump (Associate), Philadelphia, Pa

Dr Wilham R Perkins (Associate), Washington, D C

Dr James Steele, Brooklyn, N Y, was reinstated as a Fellow of the College

The Executive Secretary presented an advertisement which has appeared in several Cleveland and Pittsburgh newspapers, as well as others, by the G R Pilgren Company, referring to "Professor Ernest S Bishop, M D, Fellow of the American College of Physicians" It was pointed out that Dr Bishop had been a Fellow of the College, but that he has been dead for several years The Pilgren Company is now operated by Dr Bishop's widow, Helen E Bishop Mrs Bishop had been requested to discontinue reference to Dr Bishop as a Fellow of the American College of Physicians, especially in the present tense, but she had indicated no willingness to discontinue reference to the American College of Physicians, but expressed a willingness to change the tense to past tense

Upon motion by Dr James Alex Miller, seconded by Dr Means, and unanimously adopted, it was

RESOLVED, to have the Executive Secretary consult C Berkeley Taylor, Esq, of Philadelphia, concerning an opinion as to what action may be taken by the College to restrain the Pilgren Company from using the name of the American College of Physicians in its advertisements, and authorizing the Executive Secretary to pay whatever legal fee is necessary

President White reported the receipt of the report on Pediatric Education by the Committee on Medical Care for Children, White House Conference on Child Health and Protection, and briefed the recommendations contained on Pages 93 and 94 of that report

Upon motion by Dr Pincoffs, seconded by Dr C R Jones, and unanimously carried, it was

RESOLVED, that the report on Pediatric Education by the Follow-Up Committee on Section I, White House Conference on Child Health and Protection, be referred to the Committee on Public Relations with power to act, with the suggestion that the Committee may use the editorial page of the Annals of Internal Medicine as a means of expressing the sentiment of the College

Dr Piersol, Chairman of the Committee on Credentials, reported at length on the matter of the admission of candidates from the Medical Corps of the U S Army, U S Navy, and U S Public Health Service In an effort to revise the procedure to the satisfaction of the Surgeons General and of the College, President White had arranged a conference between Surgeon General Patterson of the Army and the Committee Surgeon General Patterson being unable to personally attend, appointed as his substitute, Colonel Hutton, Chief Surgeon of the Sixth Corps Area A meeting with Colonel Hutton, at which Dr Piersol, Dr S R Miller and President White were present, was held at the Drake Hotel, Chicago, on December 19 The recommendations of the Committee, to which Colonel Hutton agreed, are embodied in the following resolution, which was unanimously adopted

RESOLVED, that in the future in dealing with Officers of the Army, Navy and Public Health Service, recommendations of the Surgeon General of each respective service be accepted as sufficient qualification for candidacy of such Officers

Dr Piersol, as Chairman of the Committee on Credentials for Fellowship, presented the following list of candidates whose credentials the Committee had found adequate and whom they recommended to Fellowship On resolution regularly made seconded and unanimously carried, the following candidates were elected to Fellowship

President White reported that the Committee on Annals of Internal Medicine, including Drs Piersol, Barr and himself, had followed the directions of the Board of Regents in carrying on the Annals, and that Dr Weller had continued to act as Editor in a very satisfactory manner. There was some detailed report on President's White's part concerning the progress of the journal and the work of the Committee. He recommended that the present Committee and the present arrangement be authorized to continue at least until the completion of Volume V. The following resolution was regularly adopted.

RESOLVED, that the present Committee on Annals of Internal Medicine shall continue the present arrangement until the completion of Volume V of the Annals of Internal Medicine.

Upon invitation by President White, Dr Carl V Weller, Editor of the Annals of Internal Medicine, was present and made a report upon his work. He stated that because of his close connections previously with Dr Warthin and the editorial office of the Annals, it had been possible for him to take up the editorial work at the various stages of the successive issues without any break.

Dr Weller referred to minor changes in the Annals which had been made, including a uniform paper stock and a reduction in the cost of reprints. A change in paper stock had resulted in a saving of approximately fifty dollars per issue of the journal. He referred also to the adoption of a definite bibliographic style, uniform throughout the journal. He presented a copy of the style sheet for the examination of the Regents. His reasons for adopting this particular style included appearance in type, dignity, and its being in keeping with the style of some of the higher grade European journals. Furthermore, he stated that the adopted style for the Annals has a certain individuality, distinctiveness and personality.

Dr Weller also stated that he had changed the format. The reviews now follow immediately after the abstracts, without any wastage of space. The same is being done in

connection with obituaries in the College News Notes. The printing of the Annals is paid for by the page, and the fewer blank half or quarter pages there are, the greater advantage to the College.

Dr. Weller then reported upon the receipt of papers for publication. He recalled the struggle in the earlier years to secure material enough for even small issues. The situation has utterly changed. On June 1, 1931, there were thirty-five papers on hand. Since then, Dr. Weller had received eighty-two additional scientific papers, making a total of one hundred and seventeen, not including those submitted from the Baltimore Clinical Session. Of the one hundred and seventeen papers, he had returned twenty-three. The increasing number of papers submitted had made it possible to be more and more critical about those accepted. He pointed out that regardless of how tactful an editor tries to be, there will be occasions when the rejection of a paper will aggrieve the author. He had tried to mitigate this in every possible way, particularly by giving constructive criticism. In some instances, authors had rewritten papers according to the suggestions made, and the revised papers had been acceptable for publication. From the above period, he stated he had now ninety-four papers accepted for publication. He stated he had assigned from fifty to sixty per cent of the space in the Annals to papers originating from the General Sessions of the previous Clinical Session. Certain precedence, he stated, should be given to those from the Clinical Session but a part of each journal should be used for papers received from other sources.

Dr. Weller had fifty-three acceptable manuscripts in addition to those received from the Baltimore Clinical Session, and pointed out that this quantity alone would be sufficient to run the journal for five or six months. He expressed the opinion that it is unfortunate that men should have to wait that long a time for publication of their papers. The only remedy would be to reject a larger proportion at the source. Nevertheless, the Archives of Internal Medicine, the journal most nearly comparable to ours, has been publishing articles ten or twelve months after submission.

The cost of the Annals is in proportion to the size of the journal. At the present time an issue of thirty-two hundred per month was being printed. Roughly, an issue of this size costs, per page, ten dollars. Added to this is the additional cost of producing cuts, the cost of distribution, etc. He stated that he has been making a study of reducing cuts to a minimum number, and also reducing the area or size of cuts wherever there would be no great disadvantage. Dr. Weller stated that the cost of printing had been increased \$1,659.85 for the seven months of the previous year. However, there had been one hundred and forty-eight more pages, an increase of about one-sixth in the content.

In his closing comments, Dr. Weller said "with the obvious continuous growth in prestige, power and membership on the part of the College, I do not see why the Annals should not be made the best journal on Internal Medicine in this country, if not in the world."

President White, acting as Chairman of the Committee on the Annals, stated that the Committee had felt that its function is primarily that of the selection of the Editor, and that the Committee has had no active function in relation to editorial management. The selection of the Editor and the continuance of the policies of the Annals had been the Committee's most important function. However, the Committee would want to aid the Editor in any manner he desires. President White took the opportunity to thank Dr. Weller for his extremely efficient management of the Annals, and stated that throughout the membership, it has been commented among those who have been watching the Annals that the journal has gone on without any disruption, and the journal has been growing, improving in appearance, extending its influence and taking a more decided place in medical literature in this country.

The Executive Secretary distributed mimeographed copies of the Cost Analysis of the Annals of Internal Medicine, and discussed the report in detail. The official report will be

included with the annual report submitted at the San Francisco Clinical Session, and therefore, is not reproduced here

The Executive Secretary reported that two issues of the Annals of Internal Medicine are exhausted—November, 1928, and February, 1931. The November, 1928, issue had been exhausted, due to unusually heavy demands for that issue, but the February, 1931, issue had been exhausted through some unexplained shortage in the printing office. Mr. Wiltse, Manager of the Ann Arbor Press, although he had but recently assumed such office, reported a willingness to reprint the February, 1931, number, if necessary, without cost to the College.

On motion by Dr. Brown, seconded by Dr. C. R. Jones, and unanimously carried, it was **RESOLVED**, that the Executive Secretary be instructed to advertise for fifty copies of the February, 1931, issue of the Annals, in an effort to replenish the stock, and that the cost of such advertising should be allocated to the Ann Arbor Press.

The allocation of cost to the Ann Arbor Press was included in the resolution only after it had been pointed out that it would be much less expensive to the Ann Arbor Press for us to secure these additional copies through advertising than by asking them to reprint the issue.

There was a complete discussion of the possibility of the College publishing the Clinics delivered at its Clinical Sessions. Dr. O. H. Perry Pepper and the Executive Secretary had assembled a quantity of facts concerning the possible publication of such Clinics by some of the leading medical publishers. Most of them expressed little or no interest in the project unless the College would subsidize the publication of such Clinics to such a degree as to guarantee a minimum distribution, possibly of two thousand to twenty-five hundred copies.

Upon motion by Dr. Musser, seconded by Dr. S. R. Miller, and unanimously carried, it was

RESOLVED, that the publication of Clinics by the College be deferred for at least another year.

Dr. C. R. Jones, as Chairman, presented the report of the Finance Committee. He presented a plan limiting the traveling expenses to and from meetings by Officers and members of the Board of Regents, which is embodied in the following resolution which was adopted following a motion by Dr. Piersol, seconded by Dr. Stewart.

RESOLVED, that the traveling expenses of Officers and members of the Board of Regents shall not exceed Five Dollars a day in excess of railroad fare and lower berth when traveling, and shall not exceed Ten Dollars a day during the stay at the place of meeting, this resolution to become effective as of December 19, 1931.

Dr. Jones then suggested the desirability of authority from the Board of Regents for him and the Secretary-General to complete an agreement with the Commonwealth Trust Company, of Pittsburgh, to act as custodian of the securities owned by the College, such agreement to be like that which was authorized at the previous meeting with the Bank of Pittsburgh.

Upon motion by Dr. James Alex. Miller, seconded by Dr. Pepper, and unanimously carried, it was

RESOLVED, that the Secretary-General and Treasurer be authorized to complete a trust agreement with the Commonwealth Trust Company to act as custodian of the securities belonging to the College, collect the coupons, etc., in a similar manner to the previous contract with the Bank of Pittsburgh.

President White presented the matter of the College having an exhibit at the World's Fair to be held in Chicago during 1933 under the title "A Century of Progress." A Committee from the Board of Regents had been invited by Dr. Eben J. Carey, in charge of Medical Section, Basic Science Division, Department of Exhibits, to a luncheon and an inspection tour of the plans for the exhibit. The plans are going forward under auspices which promise very active and possibly an extraordinarily interesting and profitable Exposition. A plan and diagram of the entire exhibit had been shown. In the scientific exhibit, it is proposed that a number of organizations should take part. The American Medical Association, the American College of Surgeons, and many scientific and medical institutions of this country and abroad, will have exhibits.

An invitation had been extended to the American College of Physicians to do likewise. There would be no charge to the institution for the exhibit space, but it would have to bear the expense of the preparation of the exhibit, its installation and supervision. Dr. Brown commented on a possible exhibit by the College, pointing out that an exhibit by the College, if entered, should be carefully worked up and well presented. Dr. Brown further pointed out that if the College undertakes the project, it probably would have to put it in the hands of a full-paid man, with power to act, secure information, appoint subcommittees and develop a scheme to be submitted to the College, perhaps, at their next meeting. He expressed the opinion that the College cannot well keep out of the exhibit, and that this Exposition is the most important thing we have ever had for mass education in the purposes, aims and development of Internal Medicine in the United States.

In further discussion, President White suggested the possibility of a moving picture exhibit which could be run serially to show the physician in the process of making the physical diagnosis and applying these various methods of diagnosis, along with the scientific knowledge that we have, to the human body. Dr. White went on to sketch other possibilities of practically carrying this out. The difficulty would be to concentrate on the things that would be most striking, most illustrative and most educational to the public. The exhibit, if entered, should be of the highest class and yet so devised that the man of the street could get some conception of its meaning, yet it should be of interest and value to the best informed as well.

Following thereafter was a considerable amount of discussion, engaged in freely by all members of the Board, with the result that the following resolution was presented and regularly carried.

RESOLVED, that a Committee shall be appointed to investigate the feasibility of the American College of Physicians entering an exhibit in the International Exposition, A Century of Progress, to be held in Chicago during 1933, that this Committee be informed that an appropriation of five thousand dollars, and not exceeding ten thousand dollars, would be made available for such an exhibit, if necessary, and if approved, and that this Committee shall report its findings, with plans, at the annual meeting of the College in San Francisco in April, 1932.

A further motion was regularly adopted, authorizing the President to appoint a Committee as above provided. President White appointed E. R. Loveland, Chairman, Dr. Clement R. Jones and Dr. James G. Carr.

The Secretary-General, in accordance with instructions from the Board of Regents, had drawn up the following resolutions, which were read by President White, and acted upon as later indicated.

"The Officers and Board of Regents of the American College of Physicians record with profound sorrow the death of their friend and late associate, Dr. Aldred Scott Warthin, whose death occurred on May 23, 1931.

"No history of the American College of Physicians will ever be complete without reference to Dr. Warthin's long and faithful service in the interest of the organization.

"Elected Second Vice President in 1923, he served in that capacity for two years. to be made First Vice President in 1925, a position which he occupied continuously until

the time of his death. As an Officer of the College, he brought to the counsel of the Board of Regents a keen mind which realized the needs of the College and ever sought to further its future development.

"As helpful as he was to the College in the capacity of an Officer, Dr Warthin's greatest contribution to the success of this organization was as Editor of the *Annals of Internal Medicine*. From the time that he assumed his editorial duties in the year 1923, the *Annals* progressed steadily in scientific value and importance. At the time of his death, through his able editorship and untiring labors, the *Annals of Internal Medicine* had become one of the outstanding medical journals in the English language, devoted to internal medicine and its allied branches.

"Dr Warthin was a great pathologist, an able teacher and a distinguished scientist, whose researches brought not only great credit to him, but added to the prestige of American medicine.

"To his associates on the Board of Regents, his loss is of a deeply personal nature. His wise counsel will be missed. In his death the American College of Physicians has lost a staunch supporter and a faithful and efficient Officer.

"Be it **RESOLVED**, therefore, that this resolution be spread upon the Minutes of the meeting of the Board of Regents of the American College of Physicians, and that a copy be sent to Dr Warthin's family to whom the Board of Regents express their deep and sincere sympathy."

Upon motion made by Dr Stewart, seconded by Dr C R Jones, and regularly carried, it was

RESOLVED, that the above resolution be adopted and published in the *Annals*.

The second resolution follows:

"The Officers and Board of Regents of the American College of Physicians record with profound sorrow the death of their late colleague, Dr Reynolds Webb Wilcox, on June 6, 1931.

"Dr Wilcox was one of the founders of the American College of Physicians. He had the distinction of being its first President. In this capacity he labored long and faithfully for the College. Throughout his life he retained his interest in the affairs of the College, and missed no opportunity to further its success.

"In recognition thereof be it **RESOLVED** that this resolution be spread upon the Minutes of the Board of Regents and that a copy be sent to the family of Dr Wilcox, to whom the Board of Regents wish to express their deep sympathy."

Upon motion by Dr Stewart, seconded by Dr C R Jones, and regularly carried, it was

RESOLVED, that the above resolution concerning Dr Wilcox be adopted and published in the *Annals*.

Dr Piersol pointed out that some action should be taken with reference to Dr Leonard M Murray, who had previously been a member of the Board of Regents for a long time.

On motion by Dr Bierring, seconded by Dr James Alex Miller, and unanimously carried, it was

RESOLVED, that the Secretary-General draw up a resolution to be dated as of December 20, 1931, concerning Dr Murray.

Authorization was granted by the Board of Regents for the two Committees on Credentials to hold a joint meeting three or four weeks before the San Francisco Clinical Session to prepare recommendations for elections to Fellowship and Associateship at the San Francisco meeting.

Adjournment

Attest E R LOWLAND
Executive Secretary

Acknowledgment is made of the receipt of gifts to the College Library of publications by Members, as follows

Dr Archie A Barron (Fellow), Charlotte, N C—I reprint

Dr C H Cocke (Fellow), Asheville, N C—2 reprints

Dr Carl V Vischer (Fellow) Philadelphia, Pa—I reprint

Dr A G Sullivan (Fellow), Hot Springs National Park, Ark, was elected President for 1932 of the Hot Springs-Garland County Medical Society at its annual meeting in December

In his official capacity as President of the U S Pharmacopoeial Convention, Dr Walter A Bastedo (Fellow), New York City, attended the Pharmacopoeial Conference on Vitamin Standards, January 15. After much discussion, the Conference, consisting of some 30 outstanding nutrition experts, adopted the standards arrived at by the International Conference called by the Health Organization of the League of Nations in London, June, 1931. For vitamin A the unit is 0.001 mg of carotene, for vitamin B, 10 mg of an absorption product of the antineuritic vitamin B, prepared according to the method of Seidell, for vitamin C, 0.1 cc of fresh lemon juice, and for vitamin D, 1 mg of the international standard solution of irradiated ergosterol

Dr William Engelbach (Fellow), New York City, delivered an address before the Genito-urinary section of the New York Academy on January 20, his subject being "Endocrine Factors Involved in the Development of the Genital System"

Dr A M Ornsteen (Fellow), Philadelphia, Pa, has been elected President of the Philadelphia Neurological Society for 1932. On January 11, Dr Ornsteen addressed the Men's Club of the Philadelphia Ethical Society on "Music in Medicine"

Dr C H Cocke (Fellow), Asheville, N C, is the 2nd Vice-President of the Southern Medical Association for 1932

Dr Leon T LeWald (Fellow), New York, gave an illustrated lecture on the "Evaluation of Roentgenology in Oto-Laryngology," before the recently combined section of Oto-Laryngology of the Academy of Medicine. Dr. LeWald especially stressed the value of iodized oil not only in the diagnosis, but also in the *treatment* of bronchiectasis

Dr Ralph Oakley Clock (Fellow), New York City, Adjunct Professor of Medicine at New York Polyclinic Medical School, presented a paper on "Bacteriologic Testing of Catgut Sutures" before the Section on Medical Bacteriology, Immunology and Comparative Pathology at the Thirty-third Annual Meeting of the Society of American Bacteriologists in Baltimore, Maryland, December 28-30, 1931

Dr Hyman I Goldstein (Associate), Camden, N J, had a paper on "Kinetocytes—A New Fourth Blood Element" in the January issue of the Delaware State Medical Journal

There is another paper by Dr Goldstein on "Kinetocytes" in the Medical Review of Reviews (N Y), February, 1932

At the Eleventh Annual Session of the Ohio Society of Clinical and Laboratory Diagnosis, held at Columbus, January 23, 1932, the following Fellows of the College contributed

Dr W M Sheppe, Wheeling, W Va, "Diabetic Neuritis with Paralysis,"

Dr Walter Simpson, Dayton, Ohio, "Significance of Agglutination Tests in Tularemia and Undulant Fever,"

Dr F C Hodges, Huntington, W Va, "Nephritis and Nephrosis"

Dr Neil Andrews (Fellow), Oshkosh Wis, addressed the Winnebago County Medical Society on January 15, at Mercy Hospital, on "The Heart, Past and Present"

Dr Grant O Favorite (Associate), Philadelphia, Pa, is the author of an article "Pathogen Selective Cultures in Chronic

Arthritis," which appeared in the January number of the Hahnemannian Monthly

Dr Albert F R Andresen (Fellow), Brooklyn, N Y, has recently contributed the following papers at meetings indicated

January 5, "Importance of Oral Examinations" before the Second District Dental Society, Brooklyn, N Y,

January 6, "Biliary Tract Diseases" before the Sullivan County (N Y) Medical Society,

January 7, "Pre- and Post-operative Care in Operation on the Stomach" before the Brooklyn Surgical Society and Brooklyn Society of Internal Medicine,

January 14, "Gastro-intestinal Allergy" before the Passaic County (N J) Medical Society,

January 29, "Relation between Oral Infections and Gastrointestinal Diseases" before the New York Gastroenterological Association

On February 15, Dr Andresen presided at a meeting of the Medical Association of the Greater City of New York, of which he is Chairman for Brooklyn. The speakers of the evening were Dr John B D'Albora (Fellow), Brooklyn, whose title was "The Treatment of Chronic Ulcerative Colitis," and Dr Martin E Rehfuess (Fellow), Philadelphia, whose title was "Medical Treatment of Gall Bladder Disease"

Dr Joseph C Doane (Fellow), Associate Professor of Medicine, University of Pennsylvania Graduate School of Medicine and Temple University Medical School, Philadelphia, addressed the Broome County (N Y) Medical Society at Binghamton, N Y, January 3, on "The Need for Cooperation Between the Doctor and the Nurse," on January 27, Dr Doane addressed the North End Branch of the Philadelphia County Medical Society on "Newer Methods in the Diagnosis and Treatment of Diseases of the End Arteries" and on February 4, Dr Doane addressed the Chester County (Pa) Medical Society at West Chester, on "The Future of the Community Hospital"

Dr William C Boeck (Fellow) was recently appointed Senior Attending Physician to the Los Angeles County General Hospital, and also was appointed to the Medical Faculty of the College of Medical Evangelists

On January 15, Dr Boeck read a paper on "Colitis" before the staff of the U S Naval Hospital at San Diego

The Section of Internal Medicine of the Los Angeles County Medical Association held a symposium on arthritis, February 3, 1932, with the following Los Angeles Fellows contributing

"Arthritis Due to Definite Organism,

Dr Roland S Cummings,

Discussion opened by Dr Roy Thomas,

Arthritis Due to Metabolic Disturbances,"

Dr S M Alter,

Discussion opened by Dr Paul B Roen,

Arthritis Deformans,

Dr John V Barrow,

Discussion opened by Dr William C Boeck

Dr John W Shuman (Fellow) and Dr John V Barrow (Fellow) are President and Secretary respectively of the aforementioned organization

Dr Samuel Weiss (Fellow) New York City, demonstrated before the New York Physician's Association, January 27 1932 a new Photographic Gastroscope. In addition, Dr Weiss showed for the first time a color film depicting the normal and abnormal state of the stomach

At the annual meeting of the Iowa Heart Association, held in Iowa City January 30 1932, the following Fellows of the College contributed

Dr Fred M Smith Iowa City, President's Address

Dr L R Woodward Mason City, VA Clinical Syndrome of Coronary Occlusion

Dr H W Rathe Iowa City, Cardiac Disease as Observed at the Univer

Years—Etiologic Types and Clinical Manifestations,"

Dr George B Crow Burlington, "The Prognostic Significance of Certain Signs in Chronic Heart Disease,"

Dr C D Mercer, West Union, "Diagnosis of Cardiac Arrhythmias at the Bedside,"

Dr Walter L Bierring, Des Moines, "The Lengthened Q Wave in Lead III,"

Dr Frank M Fuller, Keokuk, "Development of Valve Lesions Beginning in Childhood"

Dr Albert S Hyman (Fellow) Director of the Witkin Foundation for the Study and Prevention of Heart Disease, Beth

David Hospital, New York, N Y, was the guest speaker at the February 2 meeting of the Lackawanna County Medical Society held at Scranton, Pa. Dr Hyman's address was upon "The Irregularities of the Fetal Heart, A Phonocardiographic Demonstration"

Dr Hyman was also the guest speaker at the February 4 meeting of the Clinical Society of the Manhattan General Hospital, New York, N Y. His paper was upon "The Clinical Syndrome of Coronary Thrombosis," with a lantern slide demonstration. The paper was discussed by Dr John H Cudmore (Fellow), New York, N Y, Dr A E Parsonnet (Fellow), Newark, N J, and Dr A Yaguda (Fellow), Newark N J.

OBITUARY

DR CARL DONALD CHAPPELL

Dr Carl Donald Chappell (Associate), Flint, Michigan, died January 10, 1932, at the Graduate Hospital, Philadelphia, of carcinoma.

Dr Chappell was born in Genesee County, Michigan, March 3, 1878. He graduated from the Michigan College of Medicine and Surgery in 1905 and soon after engaged in general practice in Flint. He became interested in Roentgenology and in 1927 limited his practice to this specialty. He was roentgenologist of Hurley Hospital from 1918 to 1929, and was responsible for the planning and equipment of the splendid X-ray and Physical Therapy Departments of that Hospital. At the time of his death, in addition to the direction of his own laboratory, he was roentgenologist at St Joseph's Hospital and the Woman's Hospital.

He was a member of the Genesee County Medical Society, of which he was president in 1924, a member of the Michigan State Medical Society, and a Fellow of the American Medical Association. He was a Fellow of the Radiological Society of North America, and an Associate of the American College of Physicians since 1922.

Dr Chappell was a very progressive physician and an untiring student in his specialty. Always friendly and helpful to his colleagues, his professional life was marked by devotion to the best tenets of medical tradition. He was an exemplary citizen whose unselfish service to the community will long be remembered. He is survived by his wife, a son and a daughter.

(Furnished by

JAMES D BRUCE, M.D., F.A.C.P.,
Governor for Michigan)

The Relation of The Intestinal Tract and Diet to the Treatment of Arthritis*

By RALPH PEMBERTON, M S , M D , F A C P , and E. G. PEIRCE, A B , M D ,
Philadelphia, Pa

PART ONE

THE RELATION OF THE INTESTINAL TRACT

THE problem of arthritis is the subject of an increasing amount of attention from the laboratory as well as the clinical standpoint. Because of this, various analyses of the problem which have fallen upon somewhat barren soil are now beginning to receive the consideration they deserve. This is true of so fundamental an aspect of the problem as the classification of Nichols and Richardson,¹ first published in 1909, but only now becoming widely known, and of certain fundamental orthopedic considerations, regarding "postural exercise", having to do with the mechanism and function of the body as a whole. It is also true of the therapeutic importance of a low calorie diet in arthritis and of the etiologic importance of the

gastrointestinal tract and the therapeutic consequences secondary thereto. This dietary phase of the question was developed by one of the present writers in 1912 and in a considerable number of subsequent publications, but has recently had additional emphasis at the hands of Fletcher.² This worker has adduced evidence from the x-ray standpoint relating to the intestinal tract which necessitates a further widening of our visual angle toward the disease.

That infection plays an important rôle in arthritis and many other conditions cannot be gainsaid. The present article constitutes in no sense an attempt to minimize its proven importance. The proper emphasis placed upon the infectious factors productive of arthritis and many other conditions has resulted, however, in undue domination of this concept and lack of inquiry as to how infection operates. In many instances the background upon which infectious processes become operative is laid long before these processes actually developed. Heredity, the constitutional makeup, the bodily configuration and other factors constitute prodromata which should excite active suspicion and should usually permit of prevent-

*From the Presbyterian Hospital and from the Orthopedic Hospital and Infirmary for Nervous Diseases, Philadelphia, Pa.

Received for publication, Oct. 31, 1931.

The work here reported is part of a study on Chronic Arthritis in collaboration with Dr. Robert B. Osgood of Boston. The expenses of the investigation were defrayed by contributions from various sources, including a number of patients.

ing onset of the disease. Neglect of these considerations cannot be condoned in those who attempt to treat arthritics. It is increasingly clear that factors quite other than infection may operate to induce and perpetuate the disease. It is no longer sufficient to state that a certain organism was found in a tooth or prostate and to administer the respective vaccine. Therapeutics which begin and end here, already constitute, in the eyes of many students of the subject, evidence of unfamiliarity with it. There can be no question in retrospect that hosts of arthritics have suffered because of first, extreme advocacy of the doctrine of focal infection; second, undue insistence upon, and even radicalism in, measures based on this concept, and third, because of the consequent exclusion of other measures, including even such generic agencies as those within the field of physical therapy. From a somewhat more philosophical standpoint, inquiry is now being made as to why infection arises in certain persons, why many such persons remain apparently well, why infection produces arthritis or other disease in some individuals, and how this result is brought about. It is not possible today to give a final answer to any of these questions. It is possible, however, to outline a number of factors which are definitely involved in these problems and to indicate certain therapeutic corollaries of importance attaching to them.

It is the purpose of the present article, therefore, to analyze further some of these factors, to adduce some corroboration of the work of others in relation to these factors, and to

make more available to arthritics, through their medical advisers, certain forms of therapy which in consequence are seen to deserve greater emphasis. In this brief article only the developing aspects of the matter can be touched upon and the reader is referred to previous publications³ for fuller details.

It has been pointed out by one of the present writers that reduction of diet is followed by definite benefit in a certain proportion of arthritics. Subsequent clinical experience has further incriminated the food intake and also the gastrointestinal tract in the production of arthritis. In a long series of cases the writers and their associates have been impressed by the frequency with which anatomical, topographical and physiological abnormalities of the intestinal tract can be demonstrated in arthritics by x-ray studies.⁴ Others⁵ have made the same observation.

In a recent series of x-ray studies Fletcher² has shown, however, that under appropriate conditions of diet, these abnormal configurations of the bowel, chiefly the large bowel, return toward or to normal. This is so much the case that subjects of arthritis, characterized by bizarre configurations of the colon, may no longer be recognizable from x-rays taken in the convalescent period. The implication is plain, that this abnormal condition is probably of etiologic and pathologic importance and that therapeutic effort which does not include consideration of this phase of the problem may be either incomplete or irrelevant. It is of course appreciated that the range of normality in the configurations of

the intestinal tract is wide. Some apparently normal persons possess abnormal appearing colons. This point is wisely emphasized by radiographers. It would be improper, however, to fail to give adequate consideration to the matter on this ground alone and the analogy can well be cited of the hosts of apparently well persons who harbor abscessed teeth. It should also be pointed out that the apparent emphasis placed here upon the large bowel, to the relative neglect of the small bowel, is referable to the fact that the former only can be visualized and studied in any detail by x-ray processes under present conditions of technique. In point of fact, the stomach shares in principle the deviations of the intestinal tract as a whole, as the gall bladder apparently may also. This statement is made to disclaim the intention of confining attention to the large bowel, as is the vogue in some circles.

In the attempt to explain the general situation above outlined Fletcher has advanced the view that the enlargement and tortuosity of the bowel encountered, are referable to an unbalanced ration and avitaminosis. In substantiation of this view he cites the observations of Rowlands,⁶ and others⁷ upon experimental animals in which these abnormalities have been produced by diets high in carbohydrate and low in protein and vitamins. An interesting phase of the question arises from the fact that these animals are prone to infection in the course of this syndrome. Indeed, Melanby and Green,⁸ have reached the conclusion that inadequacy of vitamin A is one of the essential factors in the

development of low grade infections. Tisdall et al.⁹ state that "a vitamin intake below the amount required for normal metabolism may produce conditions of ill health other than those commonly recognized as deficiency diseases." An important factor in the development of the general syndrome under discussion is the interesting observation that animals which acquire abnormalities of the bowel of the kind mentioned, fail to do so, even upon an avitamin diet, if given a ration low in carbohydrate but containing an adequate protein content.

Fletcher observes that these several factors have been precisely those which, partly by intent and partly incidentally, have characterized the type of diet long advocated by one of the present writers in suitable cases of arthritis. It is therefore wholly conceivable that the vitamins may play an important contributory rôle in the development of this syndrome. The problem is complicated, however, and it is not possible as yet to dogmatize as to the relative importance of the three factors mentioned.

With the aim of attempting further analysis of the question twelve cases of chronic arthritis were studied and are here cited, in which the bowel showed more or less return toward normal, as described by Fletcher, following successful treatment of the arthritic subject. They definitely confirm Fletcher's conclusions in this respect. Some of the x-rays illustrating the changes in the configurations of the bowel are not as striking as are many of those reported by Fletcher, partly perhaps because the cases were not treated with this end in view and

partly because of differences in the time intervals or other factors. Some are even more graphic. It is noteworthy, however, that when the x-rays of the first nine cases were presented at random without any data to the writers, it was possible, by observing the x-ray of the bowel alone, to select in each instance the picture taken during ill-health and that taken during or after convalescence. Typical x-rays are appended.

The lines of treatment in these cases differed and it becomes desirable to attempt some preliminary evaluation of the relative influence of the therapeutic factors operative. If, for example, some cases of arthritis illustrate the phenomenon of the return of an enlarged and tortuous bowel toward normal, following removal of focal infection alone or the use of physical therapy, somewhat broader relationships might be entertained. The following cases do not all permit, as yet, of final conclusions but the etiologic and therapeutic importance of this phase of the problem justifies presentation of the data at hand.

CASE REPORTS

Case I Mrs. R. C-n-l-y, aged 32, had atrophic arthritis of twelve years duration following typhoid fever. She had no demonstrable foci and presented a typical intestinal form of case. She made a practically complete recovery on dietary control together with betterment of her gastrointestinal function and a broad program of rest, physical therapy and tonic medication. The colon was long and dilated, with marked cecal stasis. This picture yielded radically to treatment and an x-ray taken during convalescence showed a graphic contrast.

Case II Mrs. H--K, aged 55, hypertrophic arthritis, in menopause. She had no demonstrable foci but a long dilated colon with marked ptosis. This patient improved

clinically on a balanced regimen of rest, diet, improvement of intestinal function, massage, heat and postural exercises. The x-rays taken during ill-health and convalescence showed a marked contrast (See figures 1 and 2).

Case III Miss M. A-l-s-n, aged 65, hypertrophic arthritis. Typical intestinal case although she also had diseased tonsils. She made a complete recovery along purely dietetic lines in the presence of diseased tonsils. The gastrointestinal x-ray showed a long colon which improved markedly, coincidentally with convalescence.

Case IV Mr. W. A-st-g, aged 31, had severe atrophic arthritis of four years duration and wide spread involvement. The tonsils had been removed four years before. On admission he presented prostatitis and three abscessed teeth. The colon was long and dilated. The focal infections were removed or corrected, and a proper dietary was instituted, together with correction of his gastrointestinal function. A well balanced program of massage and tonic medication was established and the patient made a complete recovery. The contrasting x-ray pictures of the colon taken during ill-health and convalescence show marked differences.

Case V Miss T. G-l-n, aged 48, had widespread atrophic arthritis. She showed a marked clinical improvement on a restricted diet. The intestine showed a very marked and relatively rapid improvement coincident with her clinical improvement. Fuller details in Part 2, case XIII (See figures 3 and 4).

Case VI Mrs. Mc--m-r-a, aged 51, had hypertrophic arthritis of fifteen years duration. Her calf muscles were sore. Diseased tonsils were removed, a sinusitis was treated and several abscessed teeth were extracted. She showed a clinical improvement presumably following the above together with a regimen of regulated rest, modified diet, heat locally, general massage, and betterment of intestinal function. The bowel x-rays showed a distinct contrast.

Case VII Miss J. E-a-s, aged 55, hypertrophic arthritis with Heberden's nodes. The onset abruptly followed a tonsillectomy and appendectomy two years previously. This patient made a complete recovery upon

dietetic lines coupled with improvement of the gastrointestinal function. The x-rays of the colon taken during ill-health and convalescence showed a definite contrast.

Case VIII Mrs S H-n-y, aged 68, had hypertrophic arthritis with malum coxae senilis which caused her much pain. The muscles of her thigh were also very painful. Her diseased tonsils were treated locally. At the time of her admission her left thigh showed little rotation and flexion of her thigh caused the lumbar spine to descend. After a year of rest, diet, colonic irrigations, heat, massage and tonic medication the function of her left hip was much improved, her colon picture showed a corresponding improvement.

Case IX Mrs H St--t, aged 48, had atrophic arthritis. This patient presented a long redundant sigmoid together with marked dental infection. The case improved after removal of the teeth and then "hung

fire." Following correction of her diet and the marked intestinal stasis together with a full but well balanced program of physical therapy and tonic medication she made a complete recovery. The contrasting x-rays of the colon showed marked differences.

Case X Mrs G-st-l, aged 70, had hypertrophic arthritis. Her knees showed large overgrowth and some displacement of the tibial heads. She had diseased tonsils which were treated locally and two abscessed teeth which were removed. After this, the patient experienced a further improvement on a regulated life with periods of rest, local and general massage and a modified diet to which she was very faithful for a long time. At present, two years later, she remains in excellent condition. The x-rays of the bowel showed definite contrast.

Case XI Miss E A-h--d-ge, aged 53, had atrophic arthritis. This patient presented typical gastrointestinal invalidism

FIG 1

Case II Mrs I H--k

A case of hypertrophic arthritis with the colon showing ptoisis, lack of tone, reduplication, lack of haustra and regurgitation.

Case II Mrs I H--k

FIG 2 Case II Mrs I H--k Hypertrophic arthritis

and had lived for years on a carbohydrate diet avoiding "acids", meat, etc. The tonsils were buried and contained some pus but were not removed. She made a complete recovery along dietetic lines coupled with improvement of her gastrointestinal function. The x-ray picture of the colon showed a definite change after convalescence as compared with ill-health.

Case XII Mrs A M Gr--n, aged 57, had hypertrophic arthritis. This was purely a gastrointestinal type of case. The tonsils had been removed four years before without benefit. She made essentially a complete recovery along dietetic lines accompanied by correction of her intestinal function. The contrasting x-ray pictures of the colon taken during ill-health and convalescence show marked differences.

In few of the cases studied could any one single form of therapy be adhered to, to the exclusion of others.

It is possible, however, to evaluate with some confidence, the treatments used in each case. It is thus clear that the return of the bowel to or toward normal accompanies not only cases in which dietetics provided the dominant or exclusive therapy (cases III, V, and XI) but also cases in which the removal of focal infection (cases IV, VI and IX) and the exhibition of physiotherapy (cases II and X) played a conspicuous rôle.

It may be concluded from the data now at hand that the abnormal contour of the bowel encountered in arthritis is one consequence, probably a very frequent one, of arthritis in general, whatever its etiology. It thus follows, as elsewhere¹⁰ stressed, that once

established, the abnormal contour and, presumably abnormal function, of the bowel become an additional contributory or causative factor in perpetuating the disease. Arthritis thus may be originated by an infection, the removal of which in no way influences secondary consequences of this general nature. Furthermore, it is probable on theoretical grounds, and has been indicated on clinical grounds¹¹ that the above configurations of the intestinal tract, constitute, *de novo*, an original, exciting factor in the production of the disease. They may apparently be congenital and suggestions of this are not lacking in young children, as revealed by x-ray studies. These con-

figurations may also be acquired through pregnancy, faulty posture and the various factors that make for visceroptosis of which they often form a part. The relation of heredity and the consequent bodily makeup of the individual to this phase of the problem of arthritis becomes, therefore, of great significance and justifies the emphasis placed upon it by Osgood and his associates¹². It may be remarked that in these cases the gall bladder may be large, it may fail to empty adequately during conduction of the x-ray dye study and apparently shares with the gastrointestinal tract as a whole a condition of atony. The bile from such organs is by no means necessarily

FIG 3

Case V Miss T G-l-n

Atrophic arthritis, with the colon showing a voluminous sigmoid, an elongated transverse portion, and lack of haustral markings

Case V Miss T G-l-n

Colon of the same case of atrophic arthritis following dietetic treatment. The ascending and transverse portions are narrowed and shortened and haustral markings appear where smooth surfaces formerly showed

FIG 4 Case V Miss T G-I-n Atrophic arthritis

infected By the same token, the stomach may be atonic and present hypochlorhydria

It is to be noted that both types of arthritis illustrated the change in the x-ray pictures of the bowel taken during ill-health and convalescence

The dispassionate view to be taken is that the etiology of arthritis at large

involves a cycle in which various factors are coordinated and that no one can be justifiably stressed, etiologically or therapeutically, to the exclusion of the rest The writers desire to emphasize that any concept of arthritis which fails to entertain consideration of these broad relationships constitutes a grave injustice toward arthritics as a group

PART TWO

RECENT DEVELOPMENTS IN THE USE OF DIET

The above studies afforded an extension of experience in the use of dietetics and justify some review or recapitulation of this field of therapy in the treatment of chronic arthritis Another justification for this is to be found in the increasing emphasis now

placed upon the two main types of arthritis and the consequent desirability of determining whether diet, or indeed any measure of therapy, has application more particularly or solely to either of these types

In view of what has been said in Part One regarding the configuration of the large bowel it becomes obvious

that the food intake and the intestinal function, using that term in its widest sense, are reciprocally concerned. Emphasis has properly been placed by Osgood, by the present writers and by others, upon adequate evacuation, especially by means of colonic irrigation, of the lower intestinal tract. Unduly popular with the laity, this has had considerable exploitation at the hands of certain enthusiasts. A wholly "mechanical" view of the problem, however, is not justifiable and the question is apparently not one of purgation alone, or of "washing out" putrefactive material or bacteria from the colon. As has elsewhere been stated,³ the institution of an appropriate dietary often affords a more fundamental approach to adjustment of the labors which the intestine is asked to perform. Much or most of that which is removed by irrigation is, precisely that which is taken in by mouth. Diet constitutes a difficult chapter, not to be entered upon lightly, but in some instances it constitutes also the *sine qua non* of successful therapy. This statement is not to be interpreted as justifying narrow emphasis upon this, or upon any other, aspect of treatment, because, as will be mentioned later, a coordinated and well-balanced attack is the great desideratum.

As already stated, experience with a recent series of cases has made it possible to determine definitely whether the beneficial influence of a diet is confined to either type, thus throwing some light upon the etiology of the two types. This question will be developed by first reciting the cases concerned.

ATROPHIC CASES

Case XIII Th-r-a Ga-l-n, aged 48, had atrophic arthritis of fourteen years duration, involving all the joints of her limbs. Diseased remnants of tonsils had been removed on the ward eight months before the present admission. She was costive and had a very long, reduplicated colon with ileocecal regurgitation. The patient was rested for a week in bed in the ward, on *ward diet*, before treatment was instituted. The ward diet is such as is given in most hospitals and is fairly high in carbohydrates. Objectively the patient became definitely worse during this week and her hands and knees became more swollen and painful. After forty-eight hours on a relative fast, to be described, her hands became less swollen and more wrinkled. A further improvement in hands, knees and other joints followed the regimen below.

First and second day—juice one orange, tid, ample water

Third day—juice one orange, 1 cup coffee, 1 dram sugar

Fourth day—same as third, plus 8 ounces vegetable soup

Fifth day—same as fourth day plus 3 Uneeda biscuits

Sixth day—semi-liquid

Seventh and eighth days—1221 caloric diet

Ninth to thirty-eighth days—1465 calories

Thirty-ninth day—1800 calories

It will be noted that on bed rest plus a high carbohydrate and high caloric diet the patient became worse. On bed rest plus a low carbohydrate, low caloric diet she became promptly and definitely better. The improvement was beyond dispute and the patient volunteered similar evidence. (See Part One, case V.)

Case XIV Mrs. M. B-ne-t developed atrophic arthritis following, or soon after, an automobile accident six years prior to admission. She had typical lesions of atrophic arthritis in her hands. Injections of Coley's fluid had given her some help. The physical examination was negative except for a slight anemia. Infected tonsils and some abscessed teeth had been removed on a previous admission without benefit. During the first week of the present admission the patient was put to bed and allowed to eat the ward diet. She became decidedly worse.

as to swelling and pain in hands and knees, and was much discouraged. After three days on the orange juice regimen described under Ga-l-n (Part Two, case xiii) she showed improvement in her hands and felt better. The boggy swelling around the knuckles became much less noticeable and by the fifth day of the diet she could make a better fist. After five days on the orange juice diet she was given a day on semi-liquid diet, then for three days she was placed on 1403 calories and for the next six days on 1465 calories. She was discharged under observation very much improved as the result of diet alone, and has remained so eight months later. (See figure 5)

Case XIV Miss El-n-r As-br-ge, aged 52, came in complaining of swelling and stiffness in her left hand and wrist which she had had for six months. She had been rheumatic all her life and had suffered much from stomach trouble, as a result of which she had been living, on medical advice, largely on various forms of carbohydrate, as being the most digestible foodstuffs. She was costive and depressed. The physical examination showed the heart slightly enlarged with a slight systolic murmur transmitted to the axilla. The arthritis was of the atrophic type. Her tonsils were infected and she had one questionable tooth. For various reasons these foci were not removed. Gastrointestinal x-rays showed duodenal

FIG 5 Case XIV Mrs M B-ne-t A case of atrophic arthritis with improvement under dietetic treatment. The colon, by x-ray examination, showed marked changes coincidental with improvement.

stasis, a ptosed colon, the tip of the cecum fixed, bowel empty only after sixty-six hours. Atropine had helped her, but also made her constive. She presented the typical characteristics of the gastrointestinal invalid plus the syndrome of arthritis. Rest, colonic irrigation combined with colonic massage and a well balanced diet fairly low in carbohydrate and high in fat, with generous amounts of green vegetables and fresh fruits have been responsible for this patient's very striking recovery from her arthritic condition. Her disposition seems to have changed completely. She is now alert, cheerful and free from arthritis, adhering, though less rigidly, to the general principles of treatment.

Case XVI Mrs E. St-kd-le, aged 52, had atrophic arthritis of six years duration. This had followed diphtheria. The patient walked with a cane with great difficulty and pain,

because of flexion of her right knee to an angle of 45°. She had also a tender right wrist and some pain in the left wrist, shoulders and elbows. She was found on examination to have a systolic murmur, a rapid pulse and a blood pressure of 188/110. She had bilateral sinusitis, posterior ethmoiditis and remnants of tonsils had been left from tonsillectomy. She was treated locally and conservatively for her sinus condition without operation. This patient was very tired and depressed during the first part of her hospital stay. She exhibited improvement first following a day on a low calorie orange juice diet. Her knee gradually extended under a treatment that consisted of a diet of 1465 calories, part time bed rest, heat and cautious massage to the knee daily. The diet of 1465 calories which was used for two months was as follows:

	Calories Protein	Calories Fat	Calories Carbohydrates	Calories Total
1 1 egg, boiled	27.1	55.8		85
1 glass milk (hot)	29.8	81.8	41.6	157
30 grams bread	11.3	3.6	65.3	80
15 grams butter	6	118.6		119
250 grams orange	6.2	2.3	87.1	96
Total	75	262.1	194	535
2 Lettuce q.s.				
8 oz vegetable soup (strained)				
60 grams string beans	2	6.1	4.7	13
Mayonnaise, 1 tbsp	7.6	161.5	1.3	170
150 grams apple	18	4.2	66.4	72
1 glass milk	29.8	81.8	41.6	157
Total	41.2	253.6	114	412
3 100 grams chicken	131.6	40.9	8.6	181
50 grams spinach	4.3	19	6.7	28
50 grams beets	3.3	5	10.7	14
30 grams bread	11.3	3.6	65.3	80
15 grams butter	6	118.6		119
250 grams orange	6.2	2.3	87.1	96
Total	157.3	184.9	178.4	518
Summary				
	75	262	194	535
	41	254	114	412
	157	185	178	518
Total	273	701	486	1465

When the patient left the hospital she could walk with ease using a brace to protect the right knee from strain. She continued on the diet in modified form and later discarded the brace. She became entirely free from arthritis after following for many months the general principles laid down.

HYPERTROPHIC CASES

Case XVII Miss Mary A., aged 65, came in complaining of stiffness, aching and soreness in limbs and back, especially the knees, of five years duration. She had hypertrophic arthritis (figure 6). She gave a history of having severe eczema over a long period of time for which she had been treated by x-ray. The patient had formerly suffered from headaches. Her menopause had been attended by unpleasant manifestations. When first seen she had vertigo and was usually constipated.

The physical examination showed a slight woman, reasonably well nourished, whose hands and knees gave evidence of hypertrophic arthritis. In all respects except those to be mentioned, her examination was not noteworthy, the cardiac dullness was slightly increased to the left, a systolic murmur was heard at the aortic cartilage and at the xyphoid, loudest at apex, with a leathery first sound, she had scattered râles in her chest, her liver border was palpable, in the upright position her abdomen was full and prominent. Her legs were both "bowed", especially the right, because of external slipping of the tibial head and her feet were flat with some pronation. Gall bladder x-ray dye studies showed a non-functioning gall bladder. Gastrointestinal x-ray studies showed a tortuous colon, sigmoid dilatation and ileocecal regurgitation. She had definitely diseased tonsils which, because of her age and cardiac condition, were not removed. A study of her dietary intake revealed that she ate an average of 1709 calories. She was given bed rest with general massage three times a week together with heat and massage as needed locally. She was put on 1540 calories consisting of a generous green vegetable ration, fresh fruit, butter, cream, meat and eggs, with relatively little carbohydrate. After thirteen days this was increased to 1700 which differed from

the diet the patient had chosen for herself in being lower in carbohydrate and higher in fat. After eight days on 1700 calories the patient was allowed 1958 calories which included 1 dram of Ol morrhuae, t i d. Five days later the diet was again reduced to 1540 calories. After two months in the hospital she left on 1700 calories. During her stay she made a decided improvement in her comfort in walking. She continued on her regimen outside with steady advance in the use of her limbs and is now well, two years later. *This patient never had colonic irrigations.* A picture of her colon taken after her convalescence shows that the colon has become less distended, shortened in certain parts, and that it shows the normal haustral markings more plainly.

Case XVIII Mrs Ada G-l-t, aged 54, had hypertrophic arthritis. She was a slight, nervous woman without much reserve strength. She came in complaining of stiffness and pain in her hands, knees and back. She had suffered from arthritis for nine years. She complained of tingling of her fingers and shins. She had cramps in her arms when carrying things. Her tonsils were out. She had no demonstrable focus of infection. Her blood pressure was 130/85. Her physical examination revealed that she had a slight systolic murmur, but no cardiac enlargement. Her right kidney, or liver, or both, were palpable. She had some tenderness over the gall bladder region. Her left foot was somewhat pronated. She rocked her hips in walking though both femora flexed and rotated well. Her hands showed hypertrophic changes. X-ray of the gastrointestinal tract and colon picture by enema showed the colon to be of a contracted type. She showed no advance on a regimen of rest, massage, bakes and colonic irrigations. She gradually improved, however, on a low caloric diet, inaugurated by a four day period of orange juice, oz xii, q d. After four weeks on a restricted house diet this was repeated with the addition on the second day of 1 dram of sugar, and four fluid drams of whiskey to each portion of orange juice. This was followed by a diet of 1062 calories of such a character that it would be absorbed high in the intestine. This diet continued for two days, after which two Uneda

biscuits were added for two days. The house diet was then allowed for two days after which she was given for ten days a diet of 1500 calories, which was then raised to 1800 calories. The definite improvement in arthritic symptoms which the patient experienced at the end of her hospital stay was even more marked later after she had spent some time in a high dry altitude. She became able to lead an active life, riding horseback and entering into various pursuits, whereas when first seen she was a limping invalid. She was last seen "doing" a European art gallery on foot.

Case XIX Mrs B-r-ch, aged 52, had clear-cut hypertrophic arthritis. There were no focal infections. Her hands were involved to such an extent that she was unable to make a good fist. After being placed on the restricted diet described below, the patient became able in 6 days to flex her fingers markedly better.

First day—juice of one orange three times a day

Second day—as above plus 1 cup of clear coffee and 1 teaspoonful sugar

Third day—as above plus 8 oz of strained vegetable soup

Fourth day—as above

Fifth day—as above plus 3 Uneda biscuits

Sixth day—semi-liquid diet

Seventh day—1000 calories

Eighth to thirty-eighth day—1200 calories

After that—1465 calories

The patient showed further improvement subsequently and was quite well nine months later.

Observations made on certain of the cases studied have amplified other observations made in the army, previously reported,¹⁴ having to do with the application of dietetics in a radical manner involving underfeeding or starvation.

FIG 6 Case XVII Miss Mary A. Hypertrophic arthritis

It was observed in the army that under conditions approaching starvation a surprising degree of restoration of function sometimes took place in joints which had apparently been largely or wholly ankylosed. This ankylosis was obviously of fibrous nature but there apparently takes place at times under these circumstances a relatively rapid improvement of local physiological processes, including possibly absorption of detritus, which results in a betterment of function that may be of the first importance to the arthritic subject. Thus, in advanced cases of the Strumpell-Marie type of atrophic arthritis, the spondylitis ossificans ligamentosa of Knaggs, there is usually definite limitation of movement in hips, knees, wrists, etc. Within the bony limitations of such residual movement, however, thickening, contracture and adhesion of the joint structures may further lead to complete or nearly complete immobility. It would appear from the as yet limited number of observations available, that sharp curtailment of diet, approaching starvation, may bring about restoration of movement within the range of true joint movement remaining, to a degree which has not been regarded as possible. Some analogy to this is seen in animals suffering from experimental rachitis in which a short period of starvation inaugurates processes of regeneration in the bone notwithstanding the inevitably unfavorable prognosis as to life if the starvation be maintained.¹⁵ It is therefore valuable to cite the following two cases illustrative of this general state of affairs in arthritis.

Case XX M-r-g-t C-m-r, aged 24, had had atrophic arthritis for two years with pain and swelling in knees, ankles, hands and wrists. There was limitation of motion amounting nearly to ankylosis. All detectable foci were eliminated. She was in the hospital for two periods, the first for three months, during which time she made a limited improvement on physiotherapeutic treatment. On the next admission nearly a year later, she was put to bed and given a low caloric diet. During the regimen she was given no treatment other than rest and a low intake of food. The program was as follows:

First and second days—juice of one orange, t i d, ample water
 Third to eighth days inclusive—as above, plus 1 cup coffee, plus 2 drams of sugar.
 Ninth to eleventh day, inclusive—1078 calories
 Twelfth to fifteenth day inclusive—1196 calories.
 Sixteenth to twenty-first day inclusive—1278 calories
 Twenty-second to forty-fifth day inclusive—1480 calories

Six days after inauguration of the diet the patient had a larger range of motion in her wrists, upon measurement, and less tenderness in a swollen finger as observed by three persons. Subsequently the patient did well when able to adhere to the principles of treatment though the circumstances of her life made this difficult and sometimes impossible. She has recently married.

Case XXI C-l-a D-v-k-n, aged 27, had atrophic arthritis of thirteen years duration. Practically all joints were involved and the left hip was ankylosed, the right hip was becoming stiff and painful. The condition had been very stubborn and the patient experienced no improvement on Small's soluble antigen, on bakes, on massage or on colonic irrigation. She was given a sharp restriction of diet as follows:

First day—juice of one orange, t i d, ample water
 Second day—juice of two oranges, 2 drams sugar, t i d,
 Third day—juice of one orange, t i d, one cup of coffee, 2 drams of sugar, 8 ounces strained vegetable soup

Fourth day—as above, plus two Uneeda crackers

Fifth day—liquid ward diet

Sixth day to eighth day—house diet

Ninth day to twelfth day—1065 calories

Thirteenth to fourteenth day—house diet

Fifteenth to twenty-fifth day—1403 calories

By the fourth day there had occurred an increased range of motion in the right hip which had previously yielded to no other form of treatment. This betterment was maintained during the period of her stay in the hospital and subsequently (See also case 26 in reference 14.)

The recital of these last two cases is perhaps rather of academic than of therapeutic interest because the proportion of cases with fibrous ankylosis which would so respond is doubtless small and such cases must be carefully selected. Furthermore, the improper use of such measures might work great harm in some subjects of unstable equilibrium, especially in the presence of hidden infections, masked tuberculosis, etc.

A recital of the above series of nine cases shows clearly the undoubted influence of a restricted diet in the treatment of *properly selected* cases of arthritis. A number of cases are detailed in which no complicating form of therapy was brought to bear. The two main types of arthritis, atrophic and hypertrophic, each showed great improvement or full recovery as a result of the same measures. This implies some commonality of etiology and pathology and will be made the basis of another communication. A chief point at issue here is that to withhold the possible benefits of diet from either type, on the basis of *a priori* convictions relating to different treatment of the two types is often to manifest an injustice toward the

arthritic sufferer. *It is not recommended that cases of arthritis, en masse, be treated in this way because, as the writers have repeatedly emphasized, the successful therapy of arthritis consists in a properly coordinated use of the various measures available in this disease.*

It is particularly to be stressed that the measures approaching starvation detailed in these cases be not applied to arthritics in any wholesale way. The reader is specifically cautioned on this point. Underfeeding for any purpose is a two-edged tool which must be circumspectly used. The propriety of instituting dietetic treatment in arthritis must be determined *independently* in all cases. The factors concerned here have been discussed elsewhere at length, and the reader who contemplates applying these measures is urged to consult the references¹⁰ cited for the necessary details.

Bearing in mind the precautions emphasized, it is to be pointed out that the use of diet constitutes in many cases a foundation for other lines of therapy which alone would be futile. The state of affairs favorably influenced by a low dietary is probably present in many or most arthritics but the extent to which the influence of this measure can be brought to bear is strictly conditioned by the nature of the causes of the arthritis, the extent to which these causes can be removed, the nutrition of the patient, the existence of complications, the degree and chronicity of invalidism, the extent of the activities of the subject, and many other factors.

Finally, brief preliminary mention can be made of the fact that in a

series of four cases of arthritis representing both the atrophic and hypertrophic variety it has been possible to bring about sharp subsidence of the disease on the basis of a low caloric and low carbohydrate intake in which all vitamins were definitely excluded. Improvement was none the less rapid or marked, however, and the implication is plain that the presence of vitamins does not constitute the essential factor in the production of the benefit achieved. This observation does not exclude the possibility that the vitamin content of the diet importantly influences the development of and recovery from the syndrome discussed. The analogy of reparatory processes under conditions of starvation in rachitis induced in experimental animals by avitamin diets may have application here. At present, however, the indications are that the low caloric diet *per se* constitutes the essential factor in the experiments mentioned and that the rôle of the vitamins becomes influential in a somewhat more indirect manner and especially over long periods of time.

SUMMARY

Attention has previously been drawn to the frequency with which the syndrome of chronic arthritis, both atrophic and hypertrophic, is accompanied by enlargement and tortuosity of the large bowel. Corroboration is afforded, in the present contribution, of the work of Fletcher who has shown that, with institution of the type of diet previously described by one of the present writers, the bowel so distorted may return to or toward a normal contour. Apparently the condition de-

scribed may sometimes be congenital or it may be acquired. Once established in the course of cases of different primary etiology, the condition described may constitute an additional contributory factor in perpetuating the disease. Arthritis may thus be originated by an infection, the removal of which in no way influences secondary consequences of this nature. It is equally probable that the above configuration and ensuing dysfunction of the intestinal tract also constitute an originally exciting factor in the production of the disease.

Dietetic therapy affords the *sine qua non* of successful treatment in a large number of cases of arthritis. *Such therapy should be applied, however, to appropriate cases only, and on the basis of a familiarity with the principles concerned and with the limiting factors to which references are given in the text.*

In amplification of earlier work, it is shown that under conditions of undernutrition approaching starvation, not only may the active symptoms of the disease subside but there may be also, occasionally, an absorption of detritus or pathological exudate in or around joints, nearly or quite ankylosed, which reduces the amount of limitation to motion imposed by the existing fibrous contractures. In *suitably selected cases* the gain so achieved, though necessarily of small extent because of bony impingements and the like, may have great significance for the activities of the patient.

Finally, preliminary report is made of the fact that cases of both types of arthritis have experienced sharp im-

provement upon low calorie diets from which all vitamins were definitely excluded. While in no way negating the rôle of the vitamins in relation to the rheumatoid syndrome as a whole,

in the sense above discussed, it is clear that the reduced food intake and not the presence of vitamins primarily determined the immediate and sharp benefit observed.

Toxic Granulocytopenia, Purpura Hemorrhagica and Aplastic Anemia Following the Arsphenamines*†

By ADOLPH B LOVEMAN, A B , M D , *Ann Arbor, Michigan*

SENATOR⁷⁷ in 1888 reported four fatal cases of acute infectious pharyngitis. Unfortunately no bacteriological or hematological studies were made. Fourteen years later Brown⁷⁰ reported the first case of acute infectious pharyngitis with complete blood studies. The patient showed a marked leukopenia and on one occasion the polymorphonuclears were reduced to one per cent. From then until Schultz⁷⁶ reported his cases of agranulocytic angina, examples of an agranulocytic blood picture were described by Schwartz,⁷⁸ Turk,⁷² and Marchand.⁷⁴

As early as 1920, Moore and Foley⁷ reported agranulocytic blood pictures following the arsphenamines. Since then many cases have been added to the literature.

A voluminous literature is now available on agranulocytic angina, most of which has appeared within the past few years. One of the most complete and enlightening is that of Baldrige and Needles.⁵⁵ They are entirely justified in their condemnation of the term 'agranulocytic angina.' They

have shown very clearly and accurately that a-granulocytosis means, either an absence of a certain type of non-granular adult cell of myeloid origin (abnormal neutrophil), or else the term is derived from a-granulocyte-osis, in which case it would mean an absence of increase of granulocytes, that is a normal count. In modern medical nomenclature neither of the above interpretations is accepted. Since agranulocytic angina in the modern sense can exist without a true angina of the throat, this is added indication that Schultz's agranulocytic angina is an inadequate terminology. No doubt that which Schultz had in mind was a diminution to absence of granulocytes associated with a necrotic process in the throat, of unknown etiology, which terminated fatally. Since various factors can produce the above syndrome, which is preferably called granulocytopenia (Harkins⁵⁴), it is felt that wherever possible adjectives should indicate etiology, such as toxic or septic granulocytopenia. For the cases described by Schultz, any of a number of names are more adequate, namely, idiopathic granulocytopenia, idiopathic granulopenia, or if it is desired to emphasize the necrotic process in the throat, idiopathic granulocytopenic angina. At

*Studies and contributions of the Department of Dermatology and Syphilology of the University of Michigan Medical School, service of Dr Udo J Wile

†Received for publication, July 28, 1931

the present time evidence is against idiopathic granulocytopenic angina being a clinical entity and favors its being a syndrome caused by various etiological factors. Time alone will tell whether there is some hitherto unknown cause responsible for the condition described by Schultz.

Evans,⁵⁸ at Johns Hopkins, first reported a case of hemorrhage following arsphenamine, in 1916. At the time, however, he regarded this as a mere incidental finding. It remained for three French workers, Leredde,⁴⁸ Labbé and Langlois,³⁸ three years later, to bring this before the eyes of the medical profession.

Farley,⁹ in 1930, in reviewing the literature of all cases of bone marrow depression following the arsphenamines reviewed 39 cases and added 7, making a total of 46 cases. If, in our study cases have been uncovered which Farley failed to report, it is no fault of his, for such complications have been hidden under various titles and the articles have appeared in many languages, as well as in rather obscure magazines. It is entirely possible that certain cases have been unintentionally omitted from this report, but to our knowledge all cases available have been included. Many of the cases were unsuited for complete studies, but were used wherever possible in compiling our statistics.

A total of 64 cases of post-arsphenamine blood dyscrasias were found in the literature, with 31 deaths, a mortality of 48 per cent. Neoarsphenamine was the drug employed in 35 cases with 17 deaths, old arsphenamine was used in 10 cases with 5 deaths, sulpharsphenamine in 6

cases with 3 deaths, silver arsphenamine in 2 cases with one death, mixed arsphenamine therapy in 8 cases with 4 deaths. In addition, other arsphenamine preparations were used, the specific types of which were not stated, and in this group there were 3 cases with one death.

In the cases reviewed it was found that arsphenamine preparations attacked each element of the bone marrow, producing 30 cases of aplastic anemia with 18 deaths, 14 cases of purpura hemorrhagica with 5 deaths, and 15 cases of granulocytopenia with 6 deaths.

Under aplastic anemias have been grouped those cases in which there was a depression of all the elements composing the bone marrow, namely red blood cells, platelets, and polymorphonuclear leukocytes, whereas in the group of purpuras have been included only those cases in which the platelets were reduced. The term granulocytopenia has been reserved for those cases in which only the polymorphonuclear white cells were diminished. With the above classification in mind it is obvious that our cases of aplastic anemia include both cases of clinical purpura hemorrhagica and granulocytopenia. Our own case reports follow.

CASE REPORTS

Case I. T. Y., age 53, white male. This patient entered the hospital on August 8, 1930, because of rapidly failing vision. He gave a history of a chancre eight years before with treatment consisting of four injections of neoarsphenamine with apparently no reactions.

Essential Physical Findings. Eyes: Argall-Robertson pupils and primary optic atrophy in both eyes. Heart: Accentuation of both the aortic and pulmonary sec-

ond sounds Liver and Spleen Neither were palpable Knee Jerks Present only on reinforcement A diagnosis of central nervous system syphilis was made and he was started on treatment He received each week for four weeks an intravenous injection of old arsphenamine (0.3 gm, 0.4 gm, 0.5 gm), intramuscular injections of bismuth salicylate 2 grains, and intraspinal injections of 0.004 gms of old arsphenamine mixed with 4 to 6 cc of the patient's own spinal fluid The patient suffered no reactions following the first three courses He received his last series of injections on August 29, 1930

Cause in the Hospital 9-1-30 Complained of marked weakness associated with pain in chest, back and abdomen Temperature 101.4 degrees Fahrenheit

9-3-30 A mild stomatitis which was noted late in the evening the day before had become worse and the breath was very offensive. Blood studies revealed a marked leukopenia associated with a relative monocytosis. Only an occasional polymorphonuclear cell could be found. There was a mild secondary anemia present. The temperature was 102.4°.

9-4-30 The patient became drowsy and complained of severe sore throat and dysphagia. Blood studies were again made and no polymorphonuclears were found.

9-5-30 Blood pressure dropped 10 to 15 mms and adrenalin, minims 5, tid, was commenced

9-6-30 Throat showed a diffuse dirty gray exudate which was moderately adherent to the underlying structures. Cultures were negative for Klebs-~~I~~,offler organisms.

but showed a suggestive growth, presumably diphtheroids. These were repeated with similar interpretations. The patient was given 1 gm of sodium thiosulphate intravenously.

9-7-30 In view of the suggestive positive cultures, the patient was transferred to the Contagious Hospital and given 20,000 units of diphtheria antitoxin, after which he made an uneventful recovery. He was discharged with an essentially normal blood picture on 9-25-30

Additional Laboratory Data The blood Kahn was positive as was that upon the cerebrospinal fluid Agglutination tests were negative for *B typhosus*, *paratyphosus A* and *B*, *B abortus* and *B. melitensis* The blood culture showed no growth Non-protein nitrogen determination was 36.5 mg per 100 cc of blood X-ray examinations of the lungs were negative

Discussion of Case I In the above case there were no warning signs of arsphenamine intoxication until after the fourth injection of arsphenamine, so it is felt that the complication was unavoidable. It is unfortunate that a complete blood count was not done on entrance, for had such been done it would have been possible to know whether there was present a preexisting neutropenia. The day the patient complained of marked dysphagia and sore throat no polymorphonuclears could be demonstrated in the blood.

Blood Findings in Case I

[illegible]

stream Roberts and Kracke⁷⁶ have shown conclusively that there is first a bone marrow depression which is followed in a few days by a hematogenous demonstration of granulocytopenia. Three to four days may elapse even after this is discovered before the patient complains of any clinical symptoms. In view of the above, it is quite probable that the blood count would have shown a mild reduction in polymorphonuclear cells before the onset of the patient's symptoms. The patient suffered a temporary exhaustion of his granulocytes with a temporary failure at production of them. This, no doubt, predisposed him to infection with the ordinary bacterial flora, producing a rather marked stomatitis, ulcerative pharyngitis, and tonsillitis.

This case cannot be called one of aplastic anemia because there is an increase in the platelets and only mild diminution of the red blood cells, no more than one would ordinarily expect from any acute infection. It actually fits in somewhere between a granulocytopenia and aplastic anemia and is an excellent illustration of how arsphenamine can affect various combinations of bone marrow elements. The symptoms, however, as well as the clinical findings, were probably caused by the failure of the bone marrow to produce polymorphonuclear cells in sufficient numbers, and therefore this case is considered one of toxic (arsphenamine) granulocytopenia. There is no adequate explanation for the increase in the monocytes except that it is a well known fact that when for any reason the polymorphonuclear cell is unable to respond to an infection it

is the monocyte that takes its place.

In spite of the negative cultures for Klebs-Löffler organisms, antitoxin was given, following which the patient commenced to improve. Whether the injection of antitoxin was coincidental with the crisis or whether it stimulated the exhausted bone marrow to further proliferation of granulocytes is impossible to state, although it is felt that the former is probably true.

Several cases have been reported in the literature paralleling the above. The one that is practically identical is that reported by Wilson⁵⁹. Dodd and Wilkinson,⁴¹ Moore and Foley,⁷ Foster,³⁷ Pouzin,³⁰ Gougerot, Barthélemy and Uhry²⁷ all report cases very similar to the author's.

Case II J. M., age 19, white female. This patient entered the Department of Dermatology and Syphilology on Feb. 20, 1931, with active secondary syphilis. She had had no previous antisyphilitic treatment. Physical examination revealed in addition to a follicular and maculo-papular syphilide, a palpable spleen. The rest of the physical examination was negative with the exception of some tenderness in the left lower quadrant caused from a pelvic inflammatory disease. Laboratory findings were negative on entrance.

Treatment	2-20-31 Intravenous injection No 1, arsphenamine, 3 gm
	Intramuscular injection No 1, bismuth salicylate, grains 2
	No reaction
	2-24-31 Intravenous injection No 2 arsphenamine 4 gm
	No reaction
	2-25-31 Intravenous injection No 3 arsphenamine 5 gm

Course in the Hospital Two days follow -

ing the last injection the patient became nauseated, vomited, and complained of pain in her left lower quadrant Her temperature was 102 degrees Six hours later the temperature rose to 104° A blood count revealed 7200 white blood cells and 70 per cent polymorphonuclear cells On March 1, 1931, the patient presented a toxic erythema She was placed on sodium thiosulphate daily, forcing of fluids, saline catharsis and alkalization For the next six or seven days she ran a very stormy course, her temperature continued to climb, reaching as high as 107° Hypodermoclysis, protoclysis, and intravenous glucose were resorted to On March 8 rather marked improvement was noted, the edema of the face, which had appeared conjointly with the toxic erythema, began to disappear, as did also the rash The next day, however, the blood examination revealed a marked granulocytopenia, and the patient complained of sore gums Examination, however, revealed no ulcerations or hemorrhage Twenty-four hours later no polymorphonuclears could be demonstrated in the blood stream From March 10 to March 18 the patient received three transfusions of whole blood The appetite commenced to improve, as did the blood picture With the reappearance of the poly-

morphonuclears in the blood stream there was a disappearance of the sore gums There developed at this time a thrombophlebitis in the left arm and many subcutaneous perineal abscesses necessitating drainage Examination of the pus revealed numerous cocci and several newly-forming polymorphonuclear leukocytes On March 30 her condition had improved to such an extent that she was given her second injection of bismuth salicylate She made an uneventful recovery and was discharged on April 5, 1931

Summary The above case is that of a young girl who, the day following her third injection of old arsphenamine, developed a high fever associated with abdominal pain which was followed in a few days by a toxic erythema At the onset of this condition her blood picture was normal but there soon developed a picture of granulocytopenia associated with sore gums, but not accompanied by ulcerations or hemorrhage She ran a very stormy course, but after treatment consisting of daily injections of sodium thiosulphate, forcing of fluids, alkalization, liver extract, local mouth antiseptics, and frequent small blood transfusions, she recovered sufficiently to be discharged 39 days after the onset of symptoms

Blood Findings in Case II

Date	R B C	W B C	Hgb	Plat	Diff	Remarks
2/20/31	5,070,000	9500	85%	Normal	Polymorpho- nuclears 54% Small lymph- ocytes 5% Large lymph- ocytes 32% Monocytes 8% Eosinophiles 1%

Discussion of Case II Because of the mild anemia that developed as the condition progressed, this case, from the blood picture, is one of aplastic anemia. However, clinically it is considered one of toxic granulocytopenia for reasons similar to those in our first case. Prior to the onset of the patient's granulocytopenia, she suffered a not uncommon toxic reaction from arsphenamine, characterized by a toxic erythema, fever, vomiting and chills. At the onset the blood picture was normal, and at this time the patient did not complain of any sore gums, or

subcutaneous abscesses. However, as soon as she did, blood studies revealed a total absence of polymorphonuclear cells. Coincident with the return of the granulocytes to the blood stream, there was marked subjective and clinical improvement in the condition about the gums. The fact that granular white cells were found in the pus from the perineal abscesses may be considered an earlier sign for predicting improvement than the blood studies. Recovery in this case was no doubt materially aided by the intravenous injections of sodium thio-

sulphate and frequent small blood transfusions

Case III M D, female, aged 26 Entered the University Hospital March 31, 1931, because of severe swelling of the face, legs, sore mouth and sore throat This condition started 10 days before her admission and 24 hours after her fourth weekly injection of neoarsphenamine (0.75 gm, 0.9 gm, 0.9 gm, 0.9 gm) for primary syphilis She had run a fever of 101° to 103° F but had had no chills or jaundice The patient had been a known and treated diabetic for the past nine years Her mother is said to have pernicious anemia There was no history of any hemorrhagic tendency

Essential Physical Findings on Entrance The patient was dull and apathetic and gave every evidence of being acutely ill The entire mouth was inflamed and the gums were so tender that it was impossible to make a thorough oral examination A few superficial ulcerations were noted about the lips and tongue There was a blowing systolic murmur heard at the apex The abdomen was slightly distended The liver and spleen were not palpable The right ankle and tibial area showed pitting edema Vaginal examination and rectal examination revealed no ulcerations

Laboratory Findings on Entrance Blood W B C, 600, R B C, 4,100,000, Hgb, 80% (Sahli) Only one white cell was seen in 15 minutes examination of the stained smear Urine Trace of albumin, 3 plus sugar, 1 plus diacetic acid, 1 plus acetone Kahn test Neg (repeatedly)

Course in the Hospital On admission the patient's temperature was 103°, pulse 120, and respirations 20 Her condition seemed to be quite serious and she was immediately given a transfusion of 500 cc of blood The following day she appeared somewhat better and was placed on a soft diabetic diet, without insulin She was given sodium perborate and warm saline mouth irrigations, alternating each hour From this time on she was given daily intravenous injections of sodium thiosulphate in one gram doses She was also given adenine sulphate in doses of 0.5

gram every other day, intravenously It was difficult to get the adenine sulphate into solution Normal 1/10 hydrochloric acid was finally necessary and the first dose of adenine was given by mouth, because of the fear of giving 1/10 normal hydrochloric acid intravenously It was discovered, however, that the solution could be satisfactorily buffered, and although this brought about a milky precipitate of the adenine, nevertheless given intravenously it caused no reaction She was given every other day small blood transfusions of 250 cc Daily white blood counts showed a small peak, the rise being on April 6, when a count of 1300 was reached The patient's diabetes was well controlled without insulin until April 7 when she showed 4 plus sugar and 3 to 4 plus diacetic acid in all specimens She was consequently placed on insulin, 16 units 3 times a day, which kept her sugar free The patient seemed to show definite improvement symptomatically The swelling and pain went down remarkably, she became brighter and the extreme soreness of her mouth diminished Re-examination of the mouth on several occasions showed large quarter-dollar sized sloughing areas, on the lateral pharyngeal wall of each side The patient continued to run an elevated temperature, as high as 104° There had been no startling changes in the white blood count There was however, symptomatic improvement until the morning of April 10, when the patient suddenly complained of severe generalized abdominal pain, associated with severe distension which could not be relieved by the ordinary measures Since some form of intestinal obstruction seemed obvious, she was seen in the Department of Surgery It was felt that in view of her other conditions a laparotomy was not warranted From this time her course was steadily downhill The skin assumed a definite icteric tint which increased markedly until death The conjunctivae which were clear previously also became icteric The white blood cell count dropped and on March 11 was 500 cells per c mm Her lung fields remained clear until the morning of that day when numerous coarse moist rales were heard in each lung base

ciated with a friction rub The patient died at 2 30 P M, March 11, 1931

Diagnosis at Autopsy "Agranulocytosis" Multiple necroses and early ulcers of tongue, pharyngeal tonsils, transverse colon and rectum Sub-acute adhesive peritonitis with acute fibrinous peritonitis superimposed Localized necrotizing perisplenitis Early pyemic abscesses in spleen. Acute hyperplastic mesenteric and retroperitoneal lymphadenitis Congested aplastic bone marrow. Encapsulated tubercles in bronchial lymph nodes Subendocardial fatty degenerative infiltration Acute passive congestion and parenchymatous degeneration of all organs

and hemoglobin, together with a marked leukopenia and absence of polymorphonuclears, make this case one of true granulocytopenia To our knowledge this is the first case of this type due to arsphenamine in which the nucleotide therapy described by Reznikoff³⁸ has been employed It is interesting to note again the occurrence of diphtheria-like organisms in cultures from the throat These findings are not new Baldridge and Needles³⁹ found similar organisms in cultures

Blood Studies

Date	R B C	W B C	Hgb	Diff	Remarks
3-31-31	4,150,000	600	67%		Practically all white cells are lymphocytes, but so few that a differential is impossible
4- 1-31	5,270,000	750	80%		As above
4- 2-31		500			
4- 2-31		700			
4- 2-31		600			
4- 2-31		450			
4- 3-31	4,400,000	650	70%		32 lymphocytes and 2 polymorphonuclears on entire smear
4- 4-31		850			Lymphocytes predominate
4- 4-31		750			Lymphocytes predominate
4- 6-31		950			
4- 6-31		1150			
4- 6-31		1300			
4- 7-31		1200			
4- 8-31		900			
4- 8-31		650			
4- 8-31		850			
4- 9-31		750			Lymphocytes predominate
	5,060,000	900	93%		

Additional Laboratory Data Urine showed 2 to 3 plus sugar practically continually Highest blood sugar, 243 mg per 100 cc on March 31, 1931 Blood NPN 31.9 per 100 cc Blood chlorides 357 per 100 cc whole blood Culture from throat showed a bacillus morphologically typical of *B diphtheriae*

Discussion of Case III This case fits in classically with Schultz's description of agranulocytic angina except that here arsphenamine was no doubt the inciting etiological agent The apparently normal red blood count

from one of their cases These findings, however, are not believed to be of any great significance

There is a close similarity in this case to the first two The essential differences are that in this case there is more of a selective action on the granulocytes, as well as a longer period of depression than in cases I and II The bone marrow became so exhausted that it was unable to function With the disappearance of granulocytes from the blood stream and bone

marrow, the patient's immunity was greatly lowered and her resistance to infection was overcome. Thus there developed a stomatitis with extensive ulcerations and an ultimate fatal outcome. In short, as Roberts and Kracke⁷⁸ have shown, life is not compatible with an absence or granulocytes.

Our pathologist stated that he had never before seen such an extensive necrotizing process in a case of granulocytopenia as existed here, and no mention of such an extensive process was found in the review of the literature. Some pathologists, no doubt, would not consider this case one resulting from arsphenamine intoxication because no chemical evidence of arsenic was detected and the liver was not that of arsenical hepatitis. The present post-mortem chemical tests for arsenic were not considered sufficiently accurate to bear weight either way, and therefore were not employed. Perhaps the arsenic was stored exclusively in the bone marrow, thus accounting for the blood dyscrasia and absence of any arsenical hepatitis. Cases of bone marrow depression are too numerous in the literature for them to be mere accidental findings and thus there is no hesitancy in recording this as another one in spite of the failure to find certain classical signs of arsenical intoxication.

Case II. B. W., female, age 23. This patient entered the hospital December 19, 1929, complaining of weakness, bleeding from the gums and vagina, and marked fatigue. Six years before entrance she had had a primary syphilitic lesion. She was under constant treatment with neoarsphenamine and the heavy metals until three months before, at which time she entered a Detroit hospital. The last injection of neoarsphenamine was 10 months prior to the onset of her

symptoms. The exact number of injections is not known, but she stated that she had at least 50 injections of neoarsphenamine, together with bismuth, mercury and Bismarsen.

Essential Physical Findings. The patient was a pale undernourished woman who was mildly icteric. The tonsils were moderately enlarged. There was evidence of old hemorrhage at the gum margins and also a black line was present. The spleen was not felt. The liver was thought to be just palpable below the costal margin.

Blood Findings on Admission. RBC, 1,470,000, WBC, 2000, Hgb, 22%. Differential: polymorphonuclears, 33%, large lymphocytes, 26%, small lymphocytes, 34%, monocytes, 6%, eosinophiles, 1%.

Blood Kahn, negative. Urinalysis, negative.

A diagnosis of aplastic anemia following neoarsphenamine was made.

Course in the Hospital. Dec 23. The patient was started on adrenalin 0.4 cc. (This was increased daily until 0.7 cc. was given, after which she was maintained on this dose.) She was also placed on a high vitamin diet.

Dec 27. A transfusion of 500 cc. of citrated blood was given. Following this the temperature went to 102° and she complained of pain in the epigastrium.

Jan 3. Another transfusion of 500 cc. of blood given.

Jan 16. The patient has maintained her blood condition fairly well since the last transfusion. Bleeding from gums and nose noted.

Jan 23. Still bleeding from mucous membranes. The spleen was felt about an inch below the costal margin.

Jan 29. Transfusion of 400 cc. of citrated blood. Temperature rose to 103°.

Feb 3. Ventriculin was started (10 grams daily).

Feb 25. Still bleeding occasionally. The condition is about the same.

March 6. Vaginal bleeding noted. Condition, however, improved.

March 9. Discharged.

Since the patient's discharge she has returned frequently for observation at intervals

this has been impossible she has had blood counts taken and notified us of the results In this way it has been possible to follow her until September 2, 1930, at which time she

complained again of weakness, nervousness, and insomnia

Numerous blood studies were made, but only part of them are included below

Blood Findings in Case IV

Date	R B C	W B C	Hgb	Diff	Reticulocytes	Remarks
*10-11-29	1,280,000	2400	20%	Polymorphonuclears 43% Small monocytes 57% Large monocytes 0%

10-15-29	1,960,000	11,150	33%	Absent	Polymorphonuclears 66% Lymphocytes 24% Monocytes 6% Eosinophiles 3% Basophiles 1%	
10-17-29	2,830,000	14,500	50%	Occasional		Transfused 650
10-18-29	3,420,000	13,300	55%	Rare		cc 1 reticulo-cyte seen
10-19-29	2,850,000	18,450	51%			

Necropsy Findings Hemorrhagic diathesis of toxic origin (arsenic, mercury, bismuth?) Hemorrhagic necrotic encephalitis Multiple hemorrhages into the brain substance, meninges, subcutaneous tissue, gastric mucosa and subepicardial tissue, with hematmata in both renal pelvis Anemia Acute parenchymatous degeneration of all

Hospital he showed evidence of the above process Blood counts revealed a normal differential count, total absence of platelets, a moderate anemia, an increased bleeding time, and normal clotting time In spite of transfusions and sodium thiosulphate the patient died on his tenth day in the hospital

DISCUSSION OF CASE V

This is a typical example of purpura hemorrhagica, thus completing in this series of cases those illustrating the effect of the arsphenamines on each individual element of the bone marrow. This case cannot be called a toxic aplastic anemia in spite of the fact that there was a marked secondary type of anemia along with marked diminution of the platelets, because there was no apparent failure in the production of polymorphonuclear cells.

In the above case there were sufficient warning signs of intolerance to the drug to warrant discontinuing further therapy, and it is to be regretted that further arsphenamine was used after the appearance of these symptoms. Had immediate treatment been instituted following the first signs of intoxication the prognosis for recovery would no doubt have been greatly enhanced. Treatment, in spite of transfusions and sodium thiosulphate, proved inadequate, and the patient died, not of an aplasia of the bone marrow, nor as a result of infection, but rather because of hemorrhage. Necropsy substantiated this evidence when it showed a hyperplastic bone marrow with a diminution of the red cell line, together with multiple visceral hemorrhages. Death was no doubt due to a hemorrhagic encephalitis.

GENERAL DISCUSSIONS

Perhaps one of the most confusing and interesting problems to confront in these cases of post-arsphenamine blood dyscrasias is the etiological factor concerned. Some authors contend that it is the organic arsenic factor that is responsible whereas others feel

that it is the benzol radical, few take the attitude that both are responsible. Lawson, Jackson, and Cattana² in reporting 28 cases of inorganic arsenic poisoning have shown that inorganic arsenic may produce a marked diminution of polymorphonuclear leukocytes with a relative monocytosis. In their cases there was, in addition, a marked lowering of the platelet count and in several patients there were symptoms of gross intestinal bleeding as evidenced by bloody stools. In one case there was also a rather severe epistaxis. Wheelihan⁴² three years later reported a case of granulocytic aplasia of the bone marrow following injections of potassium arsenite in a child.

Organic arsenic obviously produces various types of bone marrow depression, as is shown by numerous cases including the author's.

Benzol is known to produce both a neutropenia accompanied by symptoms of marked sore throat, as shown by Rohner, Baldridge and Hansmann,¹ as well as purpura and aplastic anemia as shown by the same authors and also McCord,⁴⁷⁻⁴⁸ Sweeney,⁴⁹ and Selling.⁵

It appears then from such an analysis that no one drug is entirely responsible for all cases of bone marrow depression. Inorganic arsenic has been employed in medical therapeutics for centuries, but until Lawson, Jackson and Cattana² reported their case in 1925, the literature failed to reveal any cases illustrating its toxic effect on the bone marrow. Prior to Faris's³ report in 1916 no cases were found in the literature illustrating the effect of organic arsenic on the bone marrow.

Sepsis, infection, irradiation, and chemicals are each known to produce depression of the bone marrow. There are other factors to be considered, however, for otherwise blood dyscrasias following the arsphenamines would occur more frequently. It is suggested that a predisposed, weakened, hematopoietic apparatus is probably of great importance as a secondary factor in every case of bone marrow depression. There is, however, still another factor to be considered as playing a rôle in the etiology of these diseases, and this is one heretofore entirely overlooked, namely, the syphilitic infection itself. There is at present no pathological evidence to indicate that these blood dyscrasias are due to actual invasion of the bone marrow by the spirochete, yet a syphilotoxic action should always be kept in mind as a possibility.

In addition to the etiological factors mentioned above might be mentioned drug idiosyncrasy, which is supported by the fact that one form of arsphenamine may be rather well tolerated, but when one shifts to another form (as from old arsphenamine to one of the neoarsphenamine preparations), symptoms of toxicity occur.

Inorganic arsenic, organic arsenic, and benzol, then, all play a share in producing bone marrow depression. Any drug that combines more than one of the above compounds, as do the arsphenamines, probably plays a greater rôle as an etiological agent than any of the drugs individually.

Among the organic arsenicals responsible for granulocytopenia, purpura, and aplastic anemia, neoarsphenamine is the greatest offender. In our clinic, however, this was not true,

both cases followed injections of old arsphenamine. It is possible that the explanation of this lies in the fact that in our clinic more of the old arsphenamine is employed than any of the other arsphenamine preparations.

Due to a certain lack of fundamental knowledge concerning the exact function of the bone marrow elements, it is hardly possible to make an accurate classification of diseases of the bone marrow with regard to etiological agents concerned. Certainly it is not within the scope of this paper to attempt such a thing in detail. However, for the sake of clarification, a rather simple classification which is in no way complete may be mentioned.

The arsphenamines may attack any or all of the elements of the bone marrow. If the platelets alone are depressed we get symptoms of purpura, and depending upon the degree of intoxication we get either simple purpura, purpura with hemorrhage, or, should other elements of the bone marrow be affected, purpura associated with aplastic anemia. Chemical toxicity is not the chief offender, for it is well known that purpura often results from other forms of toxicity, as well as from sepsis or bacterial infection. There might also be mentioned an idiopathic group.

The red blood cells when depressed are usually accompanied by a depression of platelets, polymorphonuclear leukocytes, or all three.

When the granulocytic element of the bone marrow alone is depressed, there results a true granulocytopenia. This likewise can be caused by chemicals, infections, irradiation, and sepsis. To this also must be added the idio-

pathic group. It is in this latter group only that the agranulocytic angina of Schultz should be placed.

If the circulating toxin, infectious products, or other etiological factors depress all three bone marrow elements, namely, platelets, red blood cells and polymorphonuclear leukocytes, a picture of aplastic anemia results.

Thus, with the above in mind, it is seen that in our cases reported the arsphenamines have acted on each of the individual elements concerned. To summarize, arsphenamine may depress either the red blood cells, platelets, polymorphonuclear cells, or any combination of these.

TREATMENT

In general treatment may be divided into two main divisions, namely, prophylactic and specific. The former is by far the more important. It was amazing in reviewing the literature to note the frequency with which treatment was continued after such gross clinical findings as bleeding from the gums, petechiae, membranous sore throat, and toxic erythema. It is much wiser to refrain entirely from the further use of arsphenamine after the appearance of such signs and symptoms and to continue therapy with one of the heavy metals. Occasionally, however, it is a safe procedure to allow the patient to have a rest period of three to six months following the employment of the arsphenamine preparation, and then start in again with smaller doses of a different arsphenamine preparation.

Moore and Keidel²² have shown that often a mild neutropenia exists

after such signs and symptoms as dermatitis exfoliativa, itching, stomatitis, and purpura, and they recommend complete blood studies before continuing any form of active therapy.

At present there is no specific treatment for any of the toxic reactions resulting from the arsphenamines, but regardless of other types of therapy employed, sodium thiosulphate, one gram daily intravenously, and frequent small blood transfusions, 250 to 300 cc three to four times a week, have been found of definite value in this clinic. There has been no opportunity in our clinic for employing immuno-transfusions, that is, blood from an individual who has recovered from the condition of which the patient is a victim. This, perhaps, offers possibilities and wherever convenient and safe should be employed.

CONCLUSIONS

1. Five cases of various types of bone marrow depression following the arsphenamines are reported and discussed.

2. The term 'agranulocytic angina' is inadequate and misleading. It is suggested that granulocytopenia is a better term.

3. Inorganic arsenic, organic arsenic and benzol may each depress any or all of the elements of the bone marrow.

4. In the blood dyscrasias following the arsphenamines, the arsenic and benzol radicals are probably both responsible.

5. A predisposed hematopoietic weakness or insufficiency which in any case may be erythropoietic, thrombopoietic, granulocytopenic or any

combination of these, is perhaps an important secondary factor in the etiology of diseases of the bone marrow following arsphenamine administration

6. A syphilitic factor affecting the bone marrow is suggested as a possibility in the etiology of the blood dyscrasias in syphilitics

7 The most adequate treatment is prophylactic Sodium thiosulphate and frequent small blood transfusions offer the best means at present for combating the condition

For the privilege of presenting this paper and for many valuable suggestions, I am indebted to my chief, Dr Udo J Wile

For the privilege of presenting Cases III, IV, and V, I am indebted to Dr Cyrus C Sturgis of the Department of Internal Medicine

For many valuable suggestions, I am, likewise, indebted to Dr Raphael Isaacs of the Department of Internal Medicine

Ascending Paralysis Resulting from the Drinking of "Jamaica Ginger"; a Clinical Study of Fifty Cases*

By DELBERT H. WERDEN, M.D., *Los Angeles, Cal*

PARALYSIS resulting from the drinking of Jamaica ginger has recently presented itself in and around Los Angeles. Two hundred cases have been reported to date (March 1, 1931). This disease has been well studied and reported by various other observers since its first appearance one year ago in the Middle West and South. The cases occurring in the present so-called "epidemic" as encountered in this hospital† presented certain findings which differed from those of other authors as well as several new features which have not previously been described. In spite of a variable clinical history, the neurological findings are remarkably constant. Fifty cases have been studied in an attempt to learn more about the manifestations of the disease, and are herewith reported. An attempt has been made to emphasize the difference in the findings in my series from those already reported.

REVIEW OF THE LITERATURE

In reporting ten cases from the South, Bennett¹ considered the etiology obscure. All of his patients were corn-whisky drinkers and had taken

in addition Jamaica ginger. Of particular interest was a wide variation in the time of onset of the symptoms (3 to 42 days), and the presence of hyperactive patellar reflexes associated with absent plantar reflexes. In Bennett's opinion the disease was a type of Landry's paralysis. Harris² reported several cases occurring in an isolated village of 100 people. The findings in these cases were similar to those in Bennett's, and he suggested that the etiological factor was some recent change in the ingredients of the ginger, probably one of the higher alcohols.

Wilson³ reported a case in which the pupils were unequal, abdominal reflexes decreased but present and the Achilles' reflexes lost. He stressed the impairment of deep pain and vibration sense in the lower extremities. Although no visual disturbances were found in his case, Wilson referred to the cases of Thompson⁴ (1897) and Woods⁵ (1899) in which amblyopia resulted from ginger drinking. Goldfain⁶ emphasized the absence of Achilles' reflexes and complete loss of vibration sense in the toes with only partial loss in the legs. With the exception of the first, none of these findings was obtained in this series.

The pathology of the disease has been completely studied in the few

*Received for publication, July 20, 1931.

†Los Angeles County General Hospital.

fatal cases by Vonderahe,⁷ Jeter⁸ and Goodale and Humphreys.⁹ Vonderahe studied three fatal cases, one being uncomplicated by any other disease. The principal changes as he found them consisted of

- 1 Progressive changes in the anterior horn cells, characterized by swelling, chromatolysis and shrinking of the cell. Ventral root fibers showed degeneration of myelin sheath and axis cylinders;

- 2 Only slight involvement of the posterior horn cells,

- 3 Severe cellular degeneration in the hypoglossal and vagus nuclei and nucleus ambiguus.

Vonderahe felt that the toxin is non-infectious, first reaching the peripheral nerves, and from these traveling through the cord to the medulla. Jeter found an exudate of lymphocytes, a few polymorphonuclear cells, much engorgement of the vessels with red cells, and small deposits of fibrin in the cauda equina. His most constant finding was a fibrosis or thickening of the interstitial structure, especially the meninges of the cord, the peripheral nerves and the perineurium.

Goodale and Humphreys studied 62 patients with "Jamaica ginger paralysis" and reported the pathology in three cases. They often found fine red-brown granules in peripheral and perinuclear situations in the cytoplasm of the nerve cells. The nucleolus was frequently absent. Focal degeneration of myelin sheaths was observed only in isolated situations. The external popliteal nerve was most frequently affected, but no changes were found in any of the nerves above the gluteal fold.

ETIOLOGY

The etiology of the disease has been definitely worked out by Smith and Elvove¹⁰ who determined without doubt that triorthocresyl phosphate caused the degeneration of the myelin sheath, the axis cylinders and motor cells in the patients who were paralyzed in previous "epidemics." This compound is a stable combination of a phenol with a phosphoric acid ester, and was present in a concentration of about two per cent in the suspected "Jamaica ginger." Triorthocresyl phosphate has produced the identical clinical picture when given in small doses to rabbits, monkeys and calves.¹⁰ It has been suggested that the difference in susceptibility between rabbits and monkeys, and among different people was due to variations in degree of absorbability of the phosphate from the intestinal tract.

RELATION OF AMOUNT OF JAMAICA GINGER CONSUMED TO THE COURSE AND SEVERITY OF THE PARALYSIS

All of the patients here studied were of the lower and middle classes of people such as one finds in a general hospital. The average age was 49.6 years which was considerably higher than that given by Harris (between 20 and 40 years). Only three patients were women. A large majority were chronic users of alcohol. Accepting the statements of the patients, 5 were heavy drinkers, 25 were moderate drinkers, and 15 were light drinkers of alcohol. The remaining 5 patients were not chronic alcoholics and had taken no alcohol other than that in the Jamaica ginger. Most of these victims had been using alcohol either just before or with

the ginger, as follows 11 had been drinking heavily, 9 moderately, and 13 lightly Seventeen patients had taken no beverage other than the ginger

Jamaica ginger causing paralysis in the present epidemic was found to contain the same poison as was found previously by Smith and Elvove The ginger is sold in two or three ounce bottles and is taken principally for its high alcoholic content (80 per cent) When mixed with about four parts of water it is supposed to produce the usual "stimulating" effects of alcohol Some mix it with other forms of liquor and a few take it as a "sobering-up medicine" after an alcoholic debauch Two of the three women in the series had taken the ginger for dysmenorrhea Most of the patients were not habitual users of "Jake," having used it only one or two times before the onset of symptoms However, 13 patients were habitual ginger drinkers The amount of beverage consumed in these cases is indicated by the following

One patient	had taken	12	bottles per month	for 10 years
One patient	had taken	2	bottles per day	for 3 years
Three patients	had taken	2	bottles per day	for 6 months
One patient	had taken	4	bottles per week	for 6 months
One patient	had taken	1	bottles per day	for 1 month
One patient	had taken	2	bottles per month	for an indefinite time
One patient	had taken	6	bottles per week	for an indefinite time
One patient	had taken	3	bottles per week	for an indefinite time
One patient	had taken	2	bottles per week	for an indefinite time

In the study of these cases one was soon impressed by the great variation in the onset and course of the disease whereupon an attempt was made to learn the relation between

1 The amount and duration of the Jamaica ginger drinking,

2 The time between the drinking and the onset of the symptoms i.e. "latent period", and finally,

3 The extent and degree of the paralysis

THE AMOUNT AND DURATION OF DRINKING

The average number of two-ounce bottles ingested by the patients in this series was 5.5, and the average number of days in which they were consumed just prior to the onset of symptoms was 5.3, making the combined average about one bottle per day for five days This includes four cases in which only one bottle was taken, and eleven in which two were taken These figures are not given to show the amount of contaminated ginger necessary to cause the disease, but only to indicate the extent of the drinking in this series The assumption that patients absorb different amounts of the poison from the intestinal tract, as proposed by Smith and Elvove, makes it difficult to say how much of the phosphate is needed to cause the paralysis We know that with some patients as little as one two-ounce bot-

tle contains enough triorthocresyl phosphate to produce extensive degeneration in the peripheral nervous system

PERIOD OF ONSET

There have been different estimates regarding the number of days constituting the 'latent period' of the disease For patients having taken one

or two bottles in one or two days, the average time before the onset was 52 days, while the "latent period" for patients having taken from six to twenty bottles within seven days was 121 days. From these figures alone one would conclude that the more ginger taken the slower the onset, or that the patient works up a resistance to the poison, or perhaps that the cramps and weakness do not occur while the drinking is in progress. However, I am inclined to believe that the discrepancy is due to the fact that the patient who has been drinking for several days does not know just which of the suspected bottles of ginger contained the toxic element, and on what day he began taking the contaminated ginger. Therefore little reliance can be placed upon the history in this regard. This point is particularly well proven by the fact that in the series in which there was a large amount of ginger taken the average number of days from the drinking of the *last* bottle of Jamaica ginger to the onset of symptoms was 55 days. This last figure corresponds closely with the 52 days between the ingestion of only a *small* amount of poison and the onset of the first symptoms. However, here again one can only generalize in his conclusions, for in several cases from 22 to 29 days elapsed before the first symptoms appeared.

EXTENT OF PARALYSIS

It is also difficult to estimate the relation between the amount of ginger taken and the extent of the nervous system destruction, but an attempt is made to do so by comparing the number of patients with complete loss of

motor power and deep and superficial reflexes in a series of patients (10) who had consumed large amounts of ginger (6 to 20 bottles) with a similar series of patients (20) who had used only small amounts of ginger (1 to 3 bottles).

In those patients who had taken a much larger amount of poison, I have observed that

- 1 Motor power of the legs and the tendo Achilles' reflexes (L IV to S III), being already markedly impaired in nearly all cases having taken only small amounts of ginger, show no further loss.

- 2 Motor power of the quadriceps femoris, the patellar reflex (L II-IV) and the cremaster reflex (L I) are lost in twice as many cases.

- 3 Biceps reflex (C V, VI) is lost in 4 times as many cases.

- 4 Flexion of the wrist (C VI-TI) in 4 times as many cases.

These observations show that the degeneration is an ascending one, the height of which is somewhat proportional to the amount of triorthocresyl phosphate absorbed by the patient. Vonderahe⁷ came to the same conclusion after studying the cells in the motor nuclei of the medulla. One of our patients, a woman of 32 years, had all the findings of a degeneration which had ascended as high as the cervical cord. Abdominal and biceps reflexes were absent, and there was a complete loss of function of the hands and forearms. Fifteen days following her first symptom, she developed an aphonia and for three weeks could not speak above a whisper. Laryngoscopic examination revealed the vocal cords to be fixed in partial adduction.

Her pulse rate while lying quietly in bed varied from 60 to 120 per minute

SYMPTOMATOLOGY

Cramps, soreness and stiffness of the calves of the legs were the first symptoms in the majority (33) of the cases. About one-fourth of the patients also experienced weakness of the feet and legs at the same time, however, in most of the cases, weakness came on three days later. Sensory changes were conspicuously absent in all but three cases. The "dead" feeling of the feet described by many of the patients was found, on further questioning, to refer to loss of motion rather than to any sensory loss. Cramps of the calves of the legs occurred alone in fifteen cases, were accompanied by soreness in three cases and by stiffness in two cases. These cramps came on suddenly in the posterior crural muscles, sometimes while the patient was exercising, and were often severe enough to compel the patient to sink to the ground. The cramps were severe and painful, with a drawing sensation in the soleus, plantaris and gastrocnemius muscles. A few, whether intentionally or otherwise, have ascribed their misfortune to their occupation, and have tried to collect compensation.

Soreness in the calf muscles occurred alone in fifteen patients, was associated with stiffness in five cases and with cramps in three cases. This soreness most frequently came on after resting or on arising in the morning. All of these symptoms were moderately severe at first, increased in severity for twelve or eighteen hours, whereupon they subsided and in three days

were gone altogether. Occasionally after three or four days, and more often at night a few shooting pains developed, starting in the feet and traveling up into the hips. These lasted only a few hours and then vanished.

Weakness of the feet and legs appeared in an average of three days after the onset in most cases. The patient first noticed that his feet were beginning to "flop" and that he had difficulty in raising the feet from the floor. This weakness began in the dorsiflexors of the foot, next involved the plantarflexors, then progressed to the leg and thigh. Most observers have mentioned only the footdrop in this disease. It is my opinion that plantarflexion was impaired almost simultaneously and equally with dorsiflexion. Plantarflexion of the foot is a more passive movement than dorsiflexion, therefore impairment of this function is not noticed by the patient and is less conspicuous to the observer. I have found on physical examination both functions equally impaired. For a few days (two to nine) the weakness of the lower extremities increased, and finally the patient found his feet almost useless. He continued to hobble around with some assistance for three or four days more, then gave up and went to bed. From this point on for several months there was exceedingly little change in the patient's condition.

Weakness of the hands is an interesting phenomenon because of the consistency with which it came on after an average period of ten days from the onset of the initial symptoms. The length of this period was also found to be ten days by Smith and Elvove,¹⁰ while Bennett¹ found that this weak-

ness appeared in three days in one-half of his cases. The patient first noticed impairment of extension and flexion of the wrists and fingers. He soon was unable to button his clothes, remove his glasses, or to grasp objects with any degree of strength or precision.

Another interesting observation was made in regard to the order in which the extremities first become involved. Thirty-two patients stated that their right hand was first to weaken. In only four cases was the left hand first involved, and one of these patients was left handed. In the lower extremities the onset was about symmetrical. That the lower extremities were first affected can easily be explained by the fact that the longer neurons in the lower extremities are more susceptible to degeneration. However, the only explanation I can offer for the right hand being involved first is that the most used extremity is more prone to weakening.

NEUROLOGIC FINDINGS

In many diseases of the nervous system the examination may be disposed of in favor of a good history. In Jamaica ginger paralysis, however, the histories are exceedingly variable in contrast to the striking similarity and consistency in the clinical findings. In most cases the condition could be diagnosed on the clinical findings alone. Two patients in the series applied for compensation for their illnesses. One said he had slipped and had fallen while carrying a load up an incline, following which he developed weakness, then paralysis. The other patient said he had been hit by a

swinging beam. Both denied having taken Jamaica ginger, but had typical findings of this type of paralysis.

If the patient is only slightly disabled and is walking around, he will have a "high stepping" gait, lifting his knees high in order that the dropped feet may clear the floor. The more disabled patient is found lying with legs extended, feet "dropped" and hands lying almost useless at his side. When the arms are raised the wrists assume a typical wrist drop. The feet appear sallow, and are cold and damp. The use of the muscles of the feet is almost entirely lost. The power of the anterior, posterior and lateral crural muscles is more or less symmetrically lost (96 per cent). The anterior femoral muscles (quadriceps and sartorius) become powerless in about half of all cases. In the upper extremities both flexors and extensors of the wrists are lost in 38 per cent of the patients, while in an additional 14 per cent the extensors are more involved than are the flexors. Where the weakness in the hands is only slight, adduction and flexion of the thumbs are the only movements impaired.

Sensation was remarkably normal in nearly all cases in this series, a feature which helps to distinguish Jamaica ginger paralysis from other types of peripheral neuritis. This finding has been so constant that I have come to believe it typical of this type of neuritis, even in view of the fact that Wilson³ and Goldfain⁶ state that there is a loss of deep pain sensation in the lower extremities, and a loss of vibration sense below the knees. In many of these cases the vibration sense was acute in the toes, causing

the patient considerable distress when touched with the tuning fork. In all except five cases both exteroceptive and proprioceptive sensation was entirely normal. This clinical observation was substantiated pathologically by Vonderahe⁷ who found only minor changes in the sensory columns and nuclei. Of the five patients who did have sensory changes, four had findings which strongly suggested that either syphilis or alcoholic neuritis was the cause of the impairment (See table II).

presents no explanation for the proprioceptive loss.

Irregularity of pupils was found in 28 cases, and inequality of pupils was found in 13 cases. In only nine of these two groups of patients were there positive Wassermann reactions. The light reflex was definitely slow or absent as compared to the reaction to convergence (accommodation) in 50 per cent of the cases in this series. Only six of these had positive Wassermann tests and two more gave a history of having had syphilis, but had

TABLE II
History and Findings of Patients Showing Sensory Changes

Case	History of Lues	Wass	Pupil		Sensation	
			Contour	Light Reaction	Extero-ceptive	Proprio-ceptive
I	Yes	Neg	Irreg	Absent	Absent	Absent
II	No	Neg	Reg	Present	Present	Absent
III	Yes	Pos	Irreg	Fair	Absent	Present
IV	Yes	Pos	Irreg	Absent	Present	Absent
V	No	Pos	Irreg	Fair	Present	Absent

Case I had taken one and a half bottles of ginger a day for six months, was considered a "moderate" alcoholic, and had taken a small amount of liquor before taking the "Jake." He therefore had cause for a true alcoholic neuritis resulting in both extero- and proprioceptive loss.

Cases IV and V were obviously tabetic, which could explain the proprioceptive loss. Case III had syphilis, irregular pupils, a slow pupillary reaction to light, and had taken two bottles of ginger a day for three years. As loss of exteroceptive sensation without a loss of proprioceptive sensation is rather unusual in both Jamaica ginger neuritis and syphilis, this case was probably one of alcoholic neuritis. Case II is the only one which

negative serology. The findings of pupillary changes in so many cases and in the absence of other disease, forces one to conclude that the same process affecting other nerves is also inhibiting the pupillary reflex.

Blurring of the nasal side of the disc margin was discovered in eleven patients. In two of these the discs were definitely "choked." Nielsen and Verity¹¹ observed Argyll-Robertson pupils and optic neuritis in a patient suffering with peripheral neuritis. On the other hand Harris² and Vonderahe⁷ found no changes in the discs or cranial nerves in any of their patients. The temporal halves of the discs were pale in twelve patients in this series. In two of these patients the discs were definitely atrophic.

probably due to syphilis. One patient who had optic atrophy had been thoroughly intoxicated before taking his ten bottles of ginger, suffered moderately severe retrobulbar soreness, and had a positive Wassermann test with absent pupillary light reflexes.

In general, the deep and superficial reflexes are a fair indication of the extent of the degeneration in the peripheral nerves and anterior horn cells of the cord. The tendo Achillis reflex is the first to be lost, and was absent in all cases except one in which only the left was elicited and another in which both Achilles' reflexes were present and normal. I believe the absence of this reflex is a constant and reliable sign in this disease as in other types of peripheral neuritis, even though in Vonderahe's cases⁷ the abdominal, Achilles' and patellar reflexes were all normal.

The cremasteric reflexes are next after the Achilles' reflex to be lost, being entirely absent in half of the cases and in nine more were lost on one side. In 21 cases in which the abdominal reflexes were entirely normal the cremaster reflexes were absent, or were absent on one side and considerably decreased on the other. Abdominal reflexes were completely absent in twelve cases, and in all but one of these the cremaster reflexes were also absent. This is to be regarded as a point of considerable significance, showing the level to which the degeneration has progressed.

The patellar reflexes were lost in eighteen cases. In only four cases were these reflexes increased, a marked contrast with the findings in Bennett's¹ cases of which one half had

hyperactive reflexes. In this series the fact that in eight cases the abdominal reflexes were still present while the patellars were absent shows how sharply the height of the ascending degeneration can be estimated, since the abdominals are supplied by the eighth to the twelfth dorsal segments, while the patellars are supplied by the third and the fourth lumbar segments.

The biceps reflexes were lost in only five cases, in two of these all other reflexes were lost, and in three only the abdominal reflexes remained. Of all patients in the series, one alone had no involvement whatever of the hands. It is assumed that the biceps reflex, being less often involved than those coming from lower down the cord, further indicates the extent of the degeneration and that the extent of the damage to the nervous system can easily be estimated by a careful examination of the various deep and superficial reflexes.

CONCLUSIONS

- 1 The disease can be definitely diagnosed on the physical findings alone. The history is often unreliable and is relatively of little importance.

- 2 The flexors of the extremities are affected almost equally with the extensors.

- 3 Sensation is seldom affected.

- 4 The lesion in Jamaica ginger paralysis is more than a neuritis. Clinical and pathological findings indicate that the process is an ascending degeneration, the extent of which is proportional to the amount of the chemical absorbed from the intestinal tract, and is manifest clinically by changes in the motor power of the extremities,

TABLE I
Showing greater loss of motor power and reflexes after taking larger doses of Jamaica ginger

Per Cent of Patients With Lost Function												
				Lost Power				Lost Reflexes

Reduction in the Incidence of Syphilis Possible

“**I**S syphilis in America on the increase or on the decline? Certainly we rarely see the rupioid and malignant types of syphilis that were formerly encountered. We believe that with education of the medical profession and with proper education of the laity as to the consequences of this disease that much good has and will continue to result. We would doubly emphasize the necessity of early diagnosis and of thorough treatment along with the more general and universal use of prophylaxis. With these forward steps and with compulsory examination of all applicants for marriage, syphilis in the next twenty-five to thirty years would truly take an enormous decline. Perhaps the day will actually come with syphilis, as with typhoid fever, that the disease will be so rare that the medical schools will have difficulty in getting material for teaching purposes. This millennium however is unfortunately not yet at hand.”

—(HAROLD N. COLE, M.D. Some observation on the treatment of syphilis, *Am Jr of Syphilis*, 1932, *xvi*, 21)

Peripheral Vascular Diseases

Treatment with Acetyl-choline Hydrochloride*

By W C WATERS, M D, *Atlanta, Georgia*

UNSATISFACTORY restoration of function so frequently follows surgical amputations for the gangrene of peripheral vascular diseases that interest in the treatment of such disturbances has been revived. Samuels¹ views the gangrene in these conditions as a self-limiting process and recommends conservatism until so much tissue has been destroyed that nonfunction appears to be inevitable.

Among palliative measures which have proved beneficial may be mentioned postural exercises,² the use of Ringer's solution by duodenal tube and by hypodermoclysis,³ and the intravenous administration of sodium citrate⁴ and sodium iodide solution.⁵

In 1926, Brown⁶ introduced the use of typhoid vaccine given intravenously to determine which cases were suitable for sympathetic ganglionectomy. He determined the "vasomotor index" after the temperature had been made to rise by the injection. This is calculated as follows: The difference between the rise in mouth temperature and the elevation in cutaneous temperature divided by the rise in the mouth temperature. An index of more than two indicates a large degree of vaso-

spasm in the disease, which ganglionectomy may be expected to relieve.

Following Brown's investigations, Allen and Smithwick⁷ gave small doses of the vaccine intravenously at spaced intervals to patients having far advanced vascular lesions in whom the operation was contra-indicated because of low vasomotor indices. They observed that reactions from injections were similar to those following periarterial sympathectomy, namely, relief of pain, elevation of the surface temperature, and improvement in the appearance of the local lesions. Of the twenty-five cases treated in this manner, eighteen were markedly benefited. The objection has been offered by Spurling⁸ that the severe constitutional reaction following the injection in these patients who are already debilitated, is undesirable.

The drug, acetyl-choline hydrochloride, was first used clinically by Villaret and Justin-Besançon⁹ in 1926 in a case of Raynaud's disease, in which the course of the disturbance was markedly alleviated. These investigators later described its action, the indication for its use and the methods of administration. It is a powerful vasodilator, this effect being produced by action on the arteries and arterioles. That the capillaries are not affected is

*Received for publication, July 17, 1931.

proved by the absence of flushing of the face following its administration¹⁰ while ophthalmoscopic examination shows dilatation of the central retinal artery to twice normal size¹¹

Acetyl-choline should be given subcutaneously or intramuscularly. Administered orally, it is without effect; while given intravenously, it is highly toxic and may prove fatal¹² The dosage varies from 50 to 100 mg, repeated at twelve to twenty-four hour

intervals. As improvement in the disturbance indicates, this may be reduced to once, twice or three times weekly According to Villaret and Justin-Besançon,¹⁰ no untoward reactions have followed two thousand personally administered injections and they report its action to be maintained with repeated use

They, further, have demonstrated a return of normal color and relief of pain in the affected parts from the use

FIG 1 Gangrene involving the large toe and medial surface of the foot There is a trophic ulcer at the base of the second and third toes

of acetyl-choline in Raynaud's disease, rest pain and intermittent claudication in thrombo-angitis obliterans was relieved, and improvement of trophic lesions and an increase in the oscillographic index was obtained. They mentioned no effect on the peripheral temperature following its administration.

Since the volume of blood flow through an extremity is measured by the rate of heat elimination,¹³ the estimation of the cutaneous temperature is of extreme importance in evaluating the effectiveness of treatment in peripheral disease. Diminution of surface temperature, particularly when associated with other signs of retarded blood flow, is characteristic of these disorders and as a rule improvement in the course of the disease is accompanied by elevation of the surface temperature in the affected parts.

In the cases herein reported, surface temperatures were taken after exposing the extremities to a room temperature of 70° F for thirty minutes. Then, the bulb of a mercury thermometer was placed between the bases

of the first and second toes which were strapped together with adhesive so that the skin was in contact with the entire surface of the bulb. Readings were made after the thermometer had been in place for three minutes. This method is accurate, simple and requires no expensive apparatus.

In one to three hours following the administration of acetyl-choline to these patients the cutaneous temperature was elevated from 2° to 5° C. The mouth temperature was not affected by the injection. This elevation lasted eighteen to twenty-four hours, at the end of which there occurred a drop to the original level. Accompanying this reaction the patients experienced a sense of warmth and relief of pain in the affected extremities. The administration of the drug daily, or every other day, over a period of time produced an increase of the surface temperature to a constantly higher level, complete relief of pain and eventually disappearance of the gangrene. Since the surface temperature of an extremity is an index to the

CHART 1 Surface temperature readings in case I after the injection of 10% of acetyl-choline.

adequacy of its blood supply, a reduction in this reading after acetyl-choline has been discontinued should be accepted as an indication that the drug is still required

The disadvantages of foreign protein administration are not encountered with the use of acetyl-choline. These are (1) the lack of a uniform and constant effect, (2) the possibility of vascular occlusion during the chill, (3) the necessity for hospitalization, and (4) the undesirability of the induction of fever for debilitated patients

The following cases are selected to

illustrate the immediate rise of the peripheral temperature following an injection of acetyl-choline to those having trophic lesions resulting from obliterative vascular diseases and to demonstrate the effectiveness of the use of the drug in the treatment of these disorders

CASE REPORTS

Case I A woman, aged 46 years, was referred for treatment because of diabetic iritis. In addition to polyuria, excessive thirst and voracious appetite, she complained of pain in the feet radiating into the calves of the legs. Since there was diminution of all types of sensation in the legs, and pul-

FIG 2 Healing of gangrene and the ulcer three months later following the use of acetyl-choline

sations in the dorsalis pedis and anterior tibial arteries appeared adequate, it was thought at the time that the pain complained of was due to diabetic neuritis

Physical examination disclosed no abnormalities. The fasting blood sugar estimate was 250 mg per 100 cc and the urine contained a large amount of sugar.

Following restriction of diet and the administration of 20 units of insulin daily, the urinary sugar disappeared and the fasting blood sugar returned to a normal level.

Nevertheless, two months later she developed an ulcerative lesion at the base of the first toe of the right foot. Shortly thereafter, gangrenous areas appeared at the bases of the second and third toes and over the plantar surface of the large toe (figure 1). In spite of the presence of apparently normal pulsations in the peripheral arteries, there was blanching of the feet with elevation and rubor with dependency. The surface temperature of the right foot was 27° and of the left 28° C.

In spite of rest in bed and the use of local heat, the gangrene appeared unimproved at the end of two weeks. One hour following the intramuscular injection of 100 mg of acetyl-choline the cutaneous temperature in the feet was increased to 30° C. This elevation lasted twelve hours, at the end of which the temperature gradually

dropped to the previous level (chart 1). The administration of the drug daily during the next two weeks resulted in marked improvement in the local lesions. A continuation of the injections twice weekly for the next three months produced complete healing of ulcerations (figure 2), disappearance of postural color changes and elevation of the surface temperature to a level constantly above 29° C (chart 2).

Case II A woman, 38 years of age, complained of small painful ulcerative lesions symmetrically distributed over the tips of the first, second and third toes of the feet. These had appeared five days previously. For years she had suffered with cold feet, more pronounced in the winter.

Digital examination revealed normal pulsations in the popliteal arteries but none were felt in the dorsalis pedis and anterior tibial vessels. The cutaneous temperature of the feet was 24° C and postural color changes were marked.

The gangrene persisted in spite of the use of heat and rest in bed for a week.

One and one-half hours after the intramuscular administration of 100 mg of acetyl-choline, the surface temperature of the feet increased to 29° C (chart 3), and pulsations returned in the peripheral arteries. This reaction lasted for eighteen hours. The use of the drug in this dosage every other

CHART 2 Surface temperature readings in case I showing a higher level after the gangrene had been healed by the use of acetylcholine

day for one month resulted in healing of the gangrene and the return of arterial pulsations in the feet

Treatment was discontinued for the following two months, at the end of which time examination disclosed no signs of the previous vascular disturbance

Case III A man, 84 years of age, had complained of pain in the right leg on exercise for three years. Lately this had become steadily worse. Two weeks before the present observation he was seized with severe pain in the member which lasted twenty-four hours. This was evidently due to an acute arterial occlusion since he noticed bluish discoloration of the toes for the first time. Following this attack he suffered with constant pain in the leg which interfered with sleep.

Palpation showed absence of pulsations in the popliteal, dorsalis pedis and anterior tibial vessels of both sides while rubor with dependency and blanching with elevation of the right foot was marked. The skin over the weight bearing areas of the right foot was thickened and there was a small ulcer both on the lateral surface and on the heel.

The surface temperature of the right foot was 25° and of the left 26° C. One hour after the intramuscular administration of 100 mg of acetyl-choline the surface temperatures were 28° . There was a gradual drop to the previous level at the end of

twenty-four hours (chart 4). Marked amelioration of rest pain was obtained by the use of the drug given every other day for the next two weeks. Its continuation twice weekly during the following two months produced marked improvement in the trophic changes and complete cessation of pain. The peripheral vessels remained pulseless.

SUMMARY

Three patients having trophic lesions due to vascular disease of the extremities were treated by intramuscular injections of acetyl-choline hydrochloride. Healing of gangrenous areas, relief of pain and elevation of the surface temperature to a higher level was obtained by the use of the drug. In one case pulsations in the peripheral arteries were re-established.

In one to three hours following an injection the cutaneous temperature in the affected parts was increased 2° to 5° C. This elevation lasted eighteen to twenty-four hours and was accompanied by a sense of warmth and relief of pain in the extremities.

The advantages of the use of acetyl-choline are (1) the ease of its admin-

CHART 3 Surface temperature readings in case II after the injection of 100 mg of acetyl-choline

CHART 4 Surface temperature readings in case III after the injection of 100 mg of acetyl-choline

istration, (2) the absence of constitutional reactions following its use, and (3) the ability to maintain a constant and uniform elevation of the surface temperature by frequently repeated injections

Metastatic Malignant Tumors of the Brain*†

By HAROLD F DUNLAP, M.D., *Rochester, Minnesota*

IN THE diagnosis and treatment of tumors of the brain, one is always confronted by the possibility of any given tumor being secondary to some primary malignant tumor situated outside of the central nervous system. Many difficulties, however, are encountered in attempting to prove the metastatic origin of such a tumor. In the hope of gaining some knowledge which would aid in clinical recognition of the true nature of these lesions, a clinical, statistical, and pathologic survey of the material available at The Mayo Clinic was undertaken.

Ninety-five patients examined in The Mayo Clinic in the ten years ending January 1, 1929, were given a diagnosis of metastatic malignant tumor of the brain. This series of cases, for purposes of study, has been divided into three groups. Group 1 consisted of twenty-three cases in which complete necropsy, including examination of the brain, was performed. In each of these cases diagnosis was first made from gross appearance of the tumor; a primary malignant tumor outside of the central nervous system was found in each case, and at least one secondary malignant tumor was found within the brain. These diagnoses all were con-

firmed by microscopic examination. Group 2 consisted of forty-four cases in which there was a clinical picture of tumor of the brain but in which there was no gross or microscopic examination, of any kind, of brain tissue. However, the presence of a primary malignant tumor outside of the central nervous system was confirmed in each case by necropsy, by biopsy, or by operation at a time previous to the appearance of symptoms of tumor of the brain. This confirmatory examination included, in all cases, microscopic studies. Group 3 consisted of twenty-eight cases in which there was a clinical picture of tumor of the brain and also a clinical picture of primary malignant tumor outside of the central nervous system. In this group gross or microscopic examination of tissue was not made at the clinic. However, some of the patients previously had been operated on elsewhere, at which time a diagnosis of malignant tumor outside of the central nervous system had been made. These diagnoses in some instances had been substantiated by microscopic studies. Detailed neurologic studies were conducted in eleven cases of group 1 and in seventy-seven cases of the entire series.

In none of the ninety-five cases was there metastasis to the skull without evidence of intracranial involvement.

*Received for publication July 30, 1931.

†From the Division of Medicine, The Mayo Clinic.

and in none was the intracranial involvement by direct extension, such as occurs in cases of tumor of the nasopharynx, accessory nasal sinuses, orbits, or eyes

The diagnoses of the primary and secondary tumors of group 1 were made by the Section on Pathologic Anatomy of The Mayo Clinic. Emphasis in this study was placed on the reaction of the tissue of the brain to the presence of the tumor, rather than on study of the nature of the tumor. The first eleven cases of group 1 were selected for special pathologic study. Sections for microscopic examination were taken from several regions from the juncture of the tumor and the adjacent tissue of the brain, from the surface of the cortex at points distant from the tumor, and from the choroid plexus. Stains used in each instance were hematoxylin and eosin, iron hematoxylin, Scharlach R, toluidine blue, van Gieson's and Mann's

ANALYSIS OF MATERIAL

The cases comprising groups 2 and 3, in which the malignancy of the cerebral lesion had not been authentically determined, although the clinical picture was that of a primary malignant tumor outside of the central nervous system and a secondary tumor within the brain, have been subjected to clinical and statistical analysis. The results of the survey of the cases of group 1 are compared to a similar survey of the larger series of cases comprising groups 2 and 3.

Clinical Studies. The average age of the patients of the entire series of ninety-five cases was 47.5 years. There were only twelve patients who were less than thirty-five years of age, of

whom three were children who probably were suffering from primary tumors of the suprarenal gland. Thus, the average age of the patients falls within the accepted cancer age. In spite of the high incidence of metastasis to the brain from carcinoma of the breast, which would tend to increase the number of cases among women, cases were about evenly divided between the sexes. There were forty-nine males and forty-six females. There was an average loss of weight of 24 pounds in thirty-four cases in which the weight of the patients had been accurately recorded.

An attempt was made in those cases in which the primary lesion should have been readily recognized, as in cases of carcinoma of the breast and in those cases in which the onset of symptoms referable to the primary lesion could be fairly accurately determined, to estimate the duration of existence of the primary lesion prior to the onset of cerebral symptoms. The average thus obtained was twenty-one months for the cases of group 1, and 31.5 months for the cases of each of the other groups. The longest interval between the onset of symptoms of the primary lesion and of those of the cerebral lesion in a case of group 1 was 6.5 years, the primary tumor was a hypernephroma. The corresponding interval in a case of group 2 was nine years, the primary tumor was a carcinoma of the carotid body. The interval in a case of group 3 was twelve years, the primary tumor was a carcinoma of the breast.

The onset of cerebral symptoms had antedated the patient's visit to the clinic for an average of three months.

for the cases of group 1, and for 45 months for the cases of each of the other groups

The average length of life from the time of examination at the clinic, until death, was 35 months, and the time from onset of cerebral symptoms until death was eight months in those cases of groups 2 and 3 in which the time of death had been reported

The presenting symptoms in the entire group of ninety-five cases were directly referable to the cerebral lesion in sixty-eight and to the primary lesion in only fifteen. There were symptoms referable to both the primary and the cerebral lesion in twelve of the cases. In seven cases of group 1 in which the patients presented themselves at the clinic because of cerebral symptoms, mention was not made of symptoms referable to the primary lesion. Cerebral symptoms were merely a terminal feature in twelve cases of group 1.

The symptoms referable to the cerebral lesion most frequently complained of were headache, vomiting that often was of a projectile nature, disturbances of vision and of speech, vertigo, and transient aphasia. Headache was the predominant complaint. The clinical signs most frequently noted were monoplegic or hemiplegic paresis, cranial nerve palsy, ataxia, and Jacksonian seizures.

The frequent incidence of mental disturbance is very striking in all three groups. In study of mental disturbance, only those cases were used which had been observed by the Section on Neurology of The Mayo Clinic. Definite mental changes were observed in 75 per cent of the cases of group 1, in 45 per cent of the cases of group 2,

and in 56.5 per cent of the cases of group 3, the incidence for the entire series was 57 per cent. The mental disturbance varied from mental sluggishness, to confusion and even to stupor in the more advanced cases. Emotional disturbances of varying degree and duration were present in a smaller percentage of cases.

Of the eighty-four cases of the entire ninety-five in which the ocular fundi had been examined, choked disk was recorded in 40 per cent. Likewise, in 41 per cent of those cases of group 1 in which the fundi had been examined there was choked disk. Optic atrophy and hemianopsia were present in a smaller percentage of cases of the entire group. There were nine cases in which there were perimetric visual field defects and three cases in which optic atrophy was present.

Study of the clinical localization of the cerebral tumors failed to disclose any region of predilection for the development of metastasis in the brain (table 1). The sixteen cases of group 1, in which detailed neurologic studies had been conducted, and in which necropsy, including examination of the

*Diagnosis was of involvement of more than one region in some cases.

brain, had been performed, were the only cases in which clinical diagnosis and localization could be checked accurately against pathologic changes. The situation of the cerebral lesion was correctly diagnosed in seven of the sixteen cases. In the remaining cases of the sixteen either localizing signs were absent or dissemination of the signs led to incorrect diagnosis of an inflammatory lesion.

A clinical diagnosis of metastatic malignant tumor of the brain was made in six of the sixteen cases. In these six cases there was an obvious primary malignant tumor elsewhere than in the brain, recognizable metastasis, or a history of previous operation for a malignant tumor situated outside of the central nervous system.

A diagnosis of primary tumor of the brain had been made in five of the sixteen cases, none of which presented either symptoms or signs referable to a primary lesion elsewhere. However, the primary lesion proved to be carcinoma of the lung in three cases and carcinoma of the kidney in two cases.

In the preceding two paragraphs, eleven of a particular group of sixteen cases have been considered. In the remaining five of these sixteen cases the dissemination of signs, the paucity of localizing signs, and failure to recognize or sufficiently to consider the primary lesions led to the assumption that the cerebral manifestations were on the basis of inflammatory diseases. In one of these five cases in which a clinical diagnosis of tuberculosis of the lung, spine and brain had been made, necropsy disclosed a primary carcinoma of the lung with metastasis to four vertebrae, situated partly in the thoracic and partly in the

lumbar region, to the subjacent meninges in the thoracic region, and to the brain. In the second of the five cases, in which a diagnosis of syphilis of the central nervous system had been made, necropsy disclosed a primary carcinoma of the lung, with metastasis to the meninges covering the midbrain and cerebellum, and healed pulmonary tuberculosis. In the third of the five cases, in which the clinical diagnosis was infectious meningo-encephalitis, secondary to the toxemia of pregnancy of seven months, necropsy revealed multiple, bilateral metastatic nodules in the cerebrum and cerebellum, secondary to carcinoma of the breast, for which operation had been performed three years previously. In the fourth of the five cases, in which a clinical diagnosis of recurrent carcinoma of the sigmoid had been made, and in which at necropsy a metastatic nodule had been found in the cerebellum, a clinical diagnosis of general paralysis of the insane had been made in view of an old history of syphilis, rapidly developing and marked mental deterioration, and the presence of clinical signs considered characteristic of syphilis of the nervous system. The fifth patient of these five, who was brought to the hospital in a moribund state, was found at necropsy to have a primary carcinoma of the pancreas, with generalized carcinomatosis and multiple cerebral metastatic growths.

There were five cases in group 1 in which there was carcinomatous involvement of the meninges. Two cases in which the primary lesion was an asymptomatic carcinoma of the lung have been considered in the preceding paragraph. In a third case, one of car-

cinoma of the stomach presenting terminal cerebral manifestations, a clinical diagnosis of carcinomatous meningitis secondary to gastric carcinoma was made prior to death, and this diagnosis was substantiated at necropsy by demonstrating carcinomatous invasion of the pia-arachnoid. In a fourth case, one of carcinoma of the breast in which cerebral symptoms were terminal, but in which neurologic studies had not been conducted, necropsy disclosed carcinomatous invasion of both the dura and pia-arachnoid. A clinical diagnosis of inoperable carcinoma of the breast, with metastasis to the midbrain, was made in a fifth case, in which necropsy disclosed several regions of metastasis to the cerebral cortex; there was also metastasis to the substance of the left third cranial nerve and to the pia-arachnoid covering the midbrain with extension of the tumor cells along the pial prolongations into the subjacent brain.

Laboratory Studies There was a slight to a moderate degree of anemia in 28 per cent of eighty-eight cases in which blood counts had been made. Of eighty cases in which Wassermann tests of the blood had been made, a positive reaction occurred in only one instance.

Examination of spinal fluid had been conducted in twenty-two cases. Among these twenty-two there was one instance in which the Wassermann test of the spinal fluid was positive, but in this instance the Wassermann test of the blood was negative. Yellow spinal fluid was obtained in six cases, three of which belong in group 1, and in which, at necropsy, involvement of the ventricle or meninges by metastatic lesion was found. There were not

more than eleven cells for each cubic millimeter of spinal fluid in any case.

Roentgenologic methods failed to reveal the presence of many of the growths encountered. The entire experience was as follows. Roentgenograms of the thorax had been made in seventy-eight cases, in 47.5 per cent of which there was evidence of pathologic change. A diagnosis of primary or metastatic malignant growth of the lung was correctly made in 37 per cent of the cases. Of the fourteen cases of group 1 in which roentgenograms of the thorax had been made and in which at necropsy pulmonary metastasis had been demonstrated, evidence of pathologic change in the roentgenogram was reported in eight cases (57 per cent). However, the incorrect diagnosis of inflammatory lesion had been made in four of the eight cases.

Metastasis or other pathologic changes had been reported in 21 per cent of the sixty-three cases in which roentgenograms of the head had been made.

Pathologic Studies The lung, breast and kidney were the sites of the primary lesion in fifty-one of the ninety-five cases, an incidence of 53.6 per cent of those cases in which the site of the primary growth could be determined. Thirteen of these fifty-one cases were in group 1, that is, 25.6 per cent of the cases comprising group 1 (table 2).

It will be recalled that the nature of the primary lesion, outside of the central nervous system, was determined by microscopic studies in all cases of groups 1 and 2. The cases in which the diagnosis was carcinoma, hypernephroma or melano-epithelioma were classed together as cases of carcinoma,

TABLE 2

whereas the cases in which the diagnosis was sarcoma, lymphosarcoma, and Hodgkin's disease were classed together as cases of sarcoma. In fifty-nine cases the growths were classified as carcinomas, an incidence of 88 per cent of the cases comprising groups 1 and 2. Six cases in which the growths were classified as sarcomas and one case each in which they were classified as myeloma and as neuroblastoma accounted for the remaining 12 per cent of the cases.

In general, metastasis was widespread throughout the body. Pulmonary involvement, either primary or secondary, was proved in nineteen of the twenty-three cases which composed group 1, an incidence of 82.6 per cent of the cases. There were five cases of primary carcinoma of the lung and fourteen cases of metastasis to the lung. This leaves four cases of group 1 to be accounted for. Two of these in which metastasis to the lung did not occur, were cases of carcinomatous meningitis in which the brain tissue

proper was not invaded. Of the two remaining cases, one was a case of sarcoma which had metastasized throughout the body in the fat-bearing tissues, and the other was a case of melanopitheliomatosis.

In the cases of group 1, in which metastasis occurred to the tissue of the brain, secondary nodules were found to be scattered irregularly throughout the gray and the white matter, just as in clinical examination, so in this examination, no site of predilection for the development of metastasis was noted. The tumors were usually rather sharply demarcated from the adjacent brain tissue and often were the site of rather marked necrosis and hemorrhage. Metastasis was single in seven cases and multiple in thirteen. It seems appropriate here to call attention to the case in which more than thirty metastatic nodules were counted. In the remaining three cases the involvement was confined primarily to the pia-arachnoid (figure 1).

Microscopic examination in most instances confirmed the impression that masses were rather sharply demarcated from the adjacent tissue, but in only two cases was a definite fibrous capsule present (figures 2 and 3). The tumors were usually decidedly vascular, and there was hemorrhage into the tumor. The tumors in some instances were composed of solid masses of tumor cells undergoing various stages of degeneration, whereas in other instances the tumor cells occurred singly, or as islets of tumor cells in a well-preserved state. The amount of reaction in the tissue of the brain adjacent to the tumor appeared to vary with the size and type of the tumor, it was less in the small tumors and in the two

FIG. 1 Case 10 Small pearly white metastatic nodules scattered over inner surface of dura

FIG 2 Case 1 The zone of demarcation, with a fibrous capsule, dividing the brain below from the tumor focus above. Rarefied appearance and swollen astrocytes in the subjacent brain tissue (x 75)

FIG 3 Case 3 Demarcation zone dividing the brain tissue from the tumor focus, without a capsule of connective tissue. Rarefaction and mild glial proliferation (x 75)

cases of melano-epithelioma, as compared to the cases of carcinoma. This zone frequently presented a rarefied or sieve-like appearance (figures 4 and 5). The number and size of the blood vessels were usually increased, and frequently they formed the center of an outlying focus of tumor cells. Frequently tumor cells and scavenger cells could be demonstrated adjacent to and in the perivascular spaces of blood vessels in this zone. There was astrocytic proliferation, and in case of involvement of the gray matter, marked destruction of the ganglion cells. In the brain tissue distant from the tumor there were usually only slight changes. This zone occasionally appeared rarefied. There was usually proliferation of the astrocytes, and occasional gitter cells. Satellitosis was commonly observed in the cortex. In two cases the choroid plexus was invaded by tumor cells. There was no invasion of the meninges secondary to invasion of the tissue of the brain, except when the tumor came into direct contact with the surface of the brain. There was an occasional inflammatory reaction in the meninges, as evidenced by increased vascularity and the presence of lymphocytes, polymorphonuclear leukocytes, plasma cells, and erythrocytes, especially if the tumor was in close proximity to the surface of the brain.

In cases of carcinomatous meningitis the subarachnoid space was distended with tumor cells existing singly or as masses (figure 6). There was a moderate amount of proliferation of connective tissue. Lymphocytes, polymorphonuclear leukocytes, plasma cells and erythrocytes were found interspersed between the tumor cells. In

some sections the tumor cells were found extending along pial prolongations into the sulci and invading the subjacent cortex (figures 7 and 8). There was little reaction in the tissue of the brain except for mild, generalized glial proliferation.

COMMENT AND COMPARISON OF THIS SERIES WITH OBSERVATIONS AND OPINIONS IN THE LITERATURE

The literature dealing with secondary carcinoma and sarcoma of the brain has been ably reviewed by Kaufmann, Gallavardin and Varay, Maass, Lihenfeld and Benda, Heinemann, Beerman, Humbert and Alexieff, Walshe, Lissauer, Schwarz and Bertels, Meyer and Grant.

Krasting gave the ratio of 1:3 as the incidence of metastatic to primary tumors of the brain at the Basel Hospital for a period of thirty-five years. This figure, obtained from the post-mortem service of a large general hospital, does not hold for the clinical incidence in a large diagnostic center. Sixty-one cases of metastatic tumor of the brain and 1,308 cases of primary tumor of the brain were seen at The Mayo Clinic from 1919 to 1925 inclusive, giving a ratio of 1:20 for secondary to primary tumors of the brain. This figure is in close agreement with that of Grant, who reported an incidence of 4 per cent for secondary as compared to primary tumor of the brain from the Peter Bent Brigham Hospital.

Krasting, in a review of 12,730 postmortem examinations performed at the Basel Hospital from 1870 to 1905, reported 1,078 cases of carcinoma, in 817 of which the brain had been examined and 160 cases of sarcoma,

FIG 4 Case 11 Islets of tumor cells extending into the adjacent brain with intervening brain tissue forming the so-called transition zone ($\times 75$)

FIG 5 Case 1 Brain tissue adjacent to the tumor Rarefaction and formation of gemastite glial cells ($\times 350$)

FIG 6 Case 10 Carcinomatous meningitis, tumor cells occur either singly or as masses The subjacent cortex is represented, and there is a blood vessel running in from the surface Neither the perivascular space, nor the tissue of the brain proper is involved by the tumor cells ($\times 75$)

FIG 7 Case 6 Extensive involvement of the pia-arachnoid in a case of carcinomatous meningitis with extension of the tumor cells along the pial prolongations and involvement of the adjacent cerebellar tissue ($\times 75$)

in 118 of which the brain had been examined. The incidence of metastasis, in those cases in which the brain was examined, was 57 per cent for the group with carcinoma and 11.6 per cent for the group with sarcoma. Gallavardin and Varay placed the incidence of metastasis to the brain as once in every seventeen to eighteen cases of malignant tumor.

Metastasis in general is widespread throughout the body in those cases in which there is cerebral metastasis. The lung was involved, either primarily or secondarily in 83 per cent of those cases in this series in which necropsy was performed. This tends to substantiate Kaufmann's view that pulmonary metastasis enhances cerebral metastasis.

Metastatic growths in the brain, in those cases in which authors have given their number, usually have been multiple and diffusely scattered. Metastatic growths in the tissue of the brain were multiple in 65 per cent of my series and in 66 per cent of Globus and Selinsky's series.

The incidence of localization of the metastatic growths in various parts of the brain appears to vary with the authors' individual experience. My series discloses no especial site of localization for the metastatic growths. Gallavardin and Varay found the largest proportion of metastatic growths in the cerebrum. Ewing, in writing of carcinoma of the breast, stated that they may metastasize to any part of the brain but are especially likely to metastasize to the cerebellum. Spiller and Weisenberg found involvement of the central convolutions, the cerebellum and the temporal lobes in order of frequency in which they are named.

It is generally agreed that the tissue of the brain is more often involved than the meninges. Cranial nerves are occasionally involved, either directly through metastasis to the substance of the nerve, or indirectly at their point of emergence from the meninges, when the latter are invaded by the tumor cells.

There is considerable variation of opinion as to the amount of reaction which the presence of the tumor excites in the surrounding tissue of the brain. Fried expressed the belief that there is no reaction, that the tissue of the brain merely melts away before the advance of the tumor. Buchholz, Kolpin, and Gallavardin and Varay stated that the tissue of the brain is merely pushed aside by the advance of the tumor, without actually being destroyed and without provoking reactive phenomena. Heinemann, Conighi, Morse and Fischer have reported on this aspect of the subject. Hassin and Singer re-

FIG. 8. Case 5. Extensive neoplastic invasion of the pial archid over the surface of the brain with small foci of tumor cells penetrating the subjacent cortex (x 75).

in 118 of which the brain had been examined. The incidence of metastasis, in those cases in which the brain was examined, was 57 per cent for the group with carcinoma and 11.6 per cent for the group with sarcoma. Gallavardin and Varay placed the incidence of metastasis to the brain as once in every seventeen to eighteen cases of malignant tumor.

Metastasis in general is widespread throughout the body in those cases in which there is cerebral metastasis. The lung was involved, either primarily or secondarily in 83 per cent of those cases in this series in which necropsy was performed. This tends to substantiate Kaufmann's view that pulmonary metastasis enhances cerebral metastasis.

Metastatic growths in the brain, in those cases in which authors have given their number, usually have been multiple and diffusely scattered. Metastatic growths in the tissue of the brain were multiple in 65 per cent of my series and in 66 per cent of Globus and Selinsky's series.

The incidence of localization of the metastatic growths in various parts of the brain appears to vary with the authors' individual experience. My series discloses no especial site of localization for the metastatic growths. Gallavardin and Varay found the largest proportion of metastatic growths in the cerebrum. Ewing, in writing of carcinoma of the breast, stated that they may metastasize to any part of the brain but are especially likely to metastasize to the cerebellum. Spiller and Weisenberg found involvement of the central convolutions, the cerebellum and the temporal lobes in order of frequency in which they are named.

It is generally agreed that the tissue of the brain is more often involved than the meninges. Cranial nerves are occasionally involved, either directly through metastasis to the substance of the nerve, or indirectly at their point of emergence from the meninges, when the latter are invaded by the tumor cells.

There is considerable variation of opinion as to the amount of reaction which the presence of the tumor excites in the surrounding tissue of the brain. Fried expressed the belief that there is no reaction, that the tissue of the brain merely melts away before the advance of the tumor. Buchholz, Kolpin, and Gallavardin and Varay stated that the tissue of the brain is merely pushed aside by the advance of the tumor, without actually being destroyed and without provoking reactive phenomena. Henemann, Conighi, Morse and Fischer have reported on this aspect of the subject. Hassin and Singer re-

FIG. 8. Case 5. Extensive ephibiosis of the pia-arachnoid over the side of the brain with small foci of tumor cells penetrating the substance of the cortex ($\times 75$).

ported focal (masses) and diffuse (encephalitic) lesions in cases of secondary carcinoma involving the tissue of the brain. They expressed the belief that there are generalized reactive phenomena characterized by the formation of new capillaries and proliferation of glial cells, and that there are degenerative changes in the ganglion cells most marked in the tissue of the brain adjacent to the tumor. In the pia-arachnoid and the choroid plexus dilated vessels were constantly present, and there were lymphocytes and gitter cells. In carcinoma of the meninges, the only pathologic element found outside the tumor cells was the presence of gitter cells, plasma cells, and macrophages in the pia-archnoid, and some proliferation of glial cells in the subjacent cortical tissue.

In the eleven cases of group 1 (paragraph 5) in this series in which detailed microscopic studies were made of sections taken from the tumor, of the adjacent tissue of the brain and of tissue of the brain distant from the tumor, the pathologic changes were essentially in agreement with those of Hassin and Singer.

The incidence of metastasis to the brain varies considerably with the situation and nature of the primary tumor. The general consensus of opinion appears to be that a primary carcinoma which gives rise to secondary tumor of the brain is most likely to be in the lung or breast, and that a primary sarcoma which gives rise to secondary growth in the brain is most likely to be in the skin or lymph nodes. Ewing and Krasting expressed the belief that melanotic tumors of the skin are especially prone to metastasize to the brain.

Maass, in a study of carcinomatous meningitis, found the stomach, lungs, and breast to be the site of the primary tumor in the order in which they are named. Fried, in a study of nineteen cases of primary carcinoma of the lung in which necropsy was performed, found cerebral metastasis in nine of eleven cases in which the brain was removed. He expressed the belief that the greater incidence of metastasis to the brain from primary malignant tumor of the lung, as compared to malignant tumors of other organs, is due to the fact that the lung acts as a filter in case of metastasis from other organs, whereas there is no natural barrier between the brain and the lung. Krasting, in a review of 130 cases of cerebral metastasis, found the primary lesion in the breast in forty cases, and in the lung in twenty-nine cases, an incidence for these two organs of 50 per cent of the entire series. I find, by including the kidney along with the lung and breast, that metastasis to the brain arose from one of these three organs in 56 per cent of Krasting's series, in 51 per cent of Grant's series, in 56.5 per cent of my series, and in 54 per cent of ninety-four cases in which the situation of the primary tumor was stated, among 108 cases which I reviewed indiscriminately from the literature.

Little difficulty should be encountered in recognizing the primary tumor when it is in the breast. Tumors in the lung and kidney, however, are prone to run an asymptomatic course. At other times, the cerebral manifestations so overshadow any symptoms which may be referable to the primary lesion that the true nature of the malady is not recognized. Fried stated

that in cases of primary carcinoma of the lung there may be symptoms referable to the thorax, the condition may run a silent course, or there may be symptoms referable to the metastases only. He expressed the belief that the clinical features are amazingly scant as compared to the amount of tissue involved and the grave nature of the lesion. His opinion was that metastasis to the brain occurs early, often masking the clinical picture of the primary lesion. In his series of cases of primary carcinoma of the lung, five patients presented symptoms due to the cerebral metastasis, the primary pulmonary lesion was discovered only accidentally following operation on the brain or at necropsy. Seven of the eight cases in my series of proved primary carcinoma of the kidney or lung with metastasis to the brain, were accompanied neither by symptoms, nor, with one exception, by clinical signs referable to the primary lesion.

Silent primary tumors, and foci of metastasis may exist in other organs, as illustrated in a case of group 3 in which a primary carcinoma of the prostate gland had metastasized to the lungs, spine and brain without symptoms referable to any lesion except the cerebral one. Cerebral symptoms had been noted for an average period of three to four months prior to the time of examination. Grant reported an average interval of four months between the onset of cerebral symptoms and the time of examination.

Choked disks occurred in 40 per cent of the cases. This is practically the same incidence of occurrence as in primary tumor of the brain. Likewise the degree of choking varies as much as in primary tumors of the brain. In

my study the cerebral symptoms and signs were frequently of a bizarre and disseminate nature, varying in intensity from day to day. In cases of multiple metastasis, a single lesion situated in a vital center may give origin to the cerebral symptoms and signs noted, the other lesions may be in silent regions. Globus and Selinsky stated that multiplicity of lesions will, in the majority of cases, lead to dissemination of objective signs.

Mental disturbance appears to be one of the outstanding features in metastatic tumors of the brain. The mental symptoms associated with metastatic tumor of the brain appear to be more marked than those associated with primary tumor of the brain. The presence and severity of mental symptoms appeared to bear possible relationship to the presence and severity of the encephalitic changes in all cases except one. Lewis reported a case in which there had been a sudden onset of psychic manifestations diagnosed by several eminent psychiatrists as a catatonic type of dementia precox, on the later development of neurologic signs, the diagnosis had been changed to encephalitis, and it was not until necropsy that it was learned that the symptoms were due to cerebral metastasis from a primary malignant growth probably in the lung. Mental symptoms occurring with metastatic tumor of the brain may be readily confused with those occurring in the ordinary type of psychosis. The similarity of such symptoms to those of general paralysis of the insane has been reported by Smith, Siefert, Liljeholm and von Heyde and Curschmann. Van Hasselt reported a case in which the diagnosis was acute dementia

Maass reported a case presenting acute psychosis with Korsakoff's syndrome. Heinemann stated that the clinical picture may be that of alcoholic intoxication. Morse expressed the belief that a psychic disturbance with stupor is often the outstanding feature. Elzholtz stated that a confusional state is the usual type of mental disturbance.

It is usually rather difficult to establish clinically that a tumor of the brain is metastatic, for the symptoms referable to the cerebral lesion are often essentially the same as those presented by a primary tumor of the brain. Moreover, the primary lesion may be a silent one, or the cerebral symptoms may be so pronounced as to obscure the less obvious symptoms and signs referable to the primary tumor. At other times, especially if there is carcinomatous involvement of the meninges, the clinical picture mimics some inflammatory lesion or functional disturbance. At times, obtaining accurate data as to symptoms, signs, and laboratory studies essential in establishing a diagnosis, is precluded by marked physical and mental deterioration of the patient.

Careful general examination should be conducted in all cases in which there is a clinical picture of tumor of the brain. Any unusual clinical or laboratory observations should be investigated further. Thus at times, by the use of the bronchoscope, proctoscope or cystoscope, it is possible to demonstrate a malignant lesion outside of the central nervous system and thus probably to save the patient from an unnecessary and hopeless operation on the brain.

Roentgenograms of the head and thorax should be made as a routine in

all cases in which tumor of the brain is suspected. There was pulmonary involvement, either of a primary or of a secondary nature, in 83 per cent of cases in this series in which necropsy was performed. Definite roentgenologic evidence of pulmonary disease was present in 51 per cent of these cases. However, in half of these cases the mistaken diagnosis of inflammatory lesion was made. Shelden has pointed out that, in searching for evidence of a primary malignant tumor outside of the central nervous system, such roentgenologic reports as healed tuberculous lesion, miliary tuberculosis, pleural adhesions, pleural effusions and pneumoconiosis should be received with suspicious reserve, and that re-examination should be made at frequent intervals to determine whether the signs are constant.

If possible, microscopic examination of tissue removed at operation in recent years should be made. Biopsy of enlarged lymph nodes, or of nodules in the skin, may disclose evidence of an extracerebral malignant tumor.

Tumor cells occasionally have been found in the spinal fluid, as in the cases of Schwarz and Bertels, Panton, Stadelmann and Meyer.

Frequently, the general appearance of the patient may furnish a clue to the diagnosis, especially if he is within the usual cancer age, if he has lost appreciable weight, or if he is at all anemic or cachectic. The usual history in a case of metastatic malignant tumor of the brain is one of precipitate onset and rapid progression of symptoms and signs, dissemination of objective signs due to multiplicity of lesions, and, from day to day, considerable fluctuation in intensity of symp-

toms and signs This picture is frequently augmented by mental disturbance, especially of a confusional type

SUMMARY

The incidence of metastatic tumor of the brain is at least 5 per cent of all tumors of the brain observed at The Mayo Clinic

There are focal (masses) and diffuse (encephalitic) lesions in the brain

The primary malignant tumor was in the lung, breast or kidney in more than 50 per cent of the cases

The primary lesion is frequently silent

Metastatic tumors of the brain often present essentially the same syndrome as primary tumors of the brain

All cases presenting clinical evidence of a tumor of the brain should be studied carefully for evidence of primary malignant tumor outside of the central nervous system

In all cases in which there is clinical evidence of tumor of the brain roentgenograms of the thorax and skull, for evidence of metastasis, should be made as a routine

Choked disks occurred in 40 per cent of the cases of metastatic tumor of the brain

Multiplicity of lesions, and consequent dissemination of signs, may lead to the assumption that the cerebral manifestations are the result of inflammatory disease

Mental symptoms, especially of a stuporous or confusional type, occurred in more than 50 per cent of the cases of metastatic malignant tumor of the brain seen at The Mayo Clinic

The incidence and intensity of mental symptoms in this series of cases appeared to bear some relationship to

the incidence of the encephalitic changes

Ephedrine in the Treatment of Narcolepsy*

By HARRY A. COLLINS, M.D., F.A.C.P., *Des Moines, Ia*

Cases of narcolepsy of various types have been described in the literature but no successful form of treatment had been recorded until Doyle's¹² recent report. In five cases of this disease the somnolent and cataleptic seizures were abolished within twenty-four hours by the use of ephedrine. In this paper I wish to present two other cases in which I have used this drug with the same success.

The first physician to write upon the subject of narcolepsy was Aretaeus who, in the first century, wrote two books upon "The Lethargics", Galen also referred to abnormal somnolence and lethargy in his writings. Dana¹ was able to find but fifty cases reported prior to 1878. Narcolepsy was first described by Westphal² in 1877, but was given its name by Gélneau³ in 1880. However, Gélneau credits Caffé⁴ with describing the first case in 1862. Fischer⁵ reported one case in 1878.

Gélneau suggested the name of "narcolepsy" for "a rare neurosis characterized by an imperious sleep of sudden onset and short duration which recurred at more or less frequent intervals". At the present time when we speak of narcolepsy we recognize a distinction between those cases of prolonged somnolence which some of

the earlier writers have reported and the true narcolepsy of today in which the diagnosis is based on two very important points, namely, that the conditions of narcolepsy and cataplexy must co-exist. Several German writers have recognized this distinction as did also Lowenfeld⁶ in 1892, Camp⁷ in 1907, Adie⁸ in 1926, Kinnier Wilson⁹ in 1928, Cave¹⁰ in 1929, and Daniels¹¹ and Doyle¹² in 1930. In 1929, Cave of the Mayo Clinic presented narcolepsy as a definite clinical entity in his group of forty-two cases which was the largest single series reported up to that time. He made the statement, "that narcolepsy is a rare condition is shown by the fact that these forty-two cases represent a total registration of 361,602 patients or one case of narcolepsy in every 8,610 patients."

Narcolepsy may be described as a clinical syndrome which consists first of irresistible attacks of sleep which may occur at any time or in any place, and of variable duration lasting from a few seconds to several hours and secondly, of cataplectic attacks which are characterized by a sudden transitory loss of muscular tonus which is usually precipitated by an emotional stimulus such as laughter, anger, excitement or exertion. During these cataplectic attacks the patient may lose complete power in the skeletal musculature and may fall to the ground in

*Received for publication August 2, 1931.

a perfectly helpless condition but in the majority of cases complete consciousness is maintained. These attacks are usually of short duration and following them the patient will be able to continue whatever he was doing before the attack. Occasionally he will merely experience the "shaky spell" without the precipitate fall and at other times only certain muscle groups will be affected rather than the entire muscular system. The narcoleptic and cataplectic attacks usually occur independently of each other. Frequently the patient will refer to the cataplectic symptoms as "shaky spells." He may complain of diplopia and dimness of vision as prodromal symptoms of the attack. Because laughing often precipitates an attack the German writers often refer to it as "lachs Schlag" or "laugh stroke." As Doyle has mentioned, perhaps it is the feeling of mirth rather than the laughter itself which precipitates the loss of muscular tonus. The disease is idiopathic but similar symptoms are not uncommonly associated with inflammatory or neoplastic diseases of the third ventricle.

Pathological changes which may occur in idiopathic narcolepsy have not yet been demonstrated. Somnolence has been noted for a long time as being associated with organic lesions at the base of the brain. As Cave has stated, the sleep of the narcoleptic patient is of a far different type than that of a patient with organic disease of the brain. Fulton and Bailey¹³ were of the opinion, after an extensive review of the subject, that sleep disturbance was the result of changes in the region of the gray matter near the Sylvian aqueduct. We may conclude from this and other data that narcolepsy is the re-

sult of a lesion in the region of the posterior portion of the third ventricle.

The etiological factors of narcolepsy are not known. It has been suggested that encephalitis, so common after the influenzal epidemic of 1918, might be a contributing factor. In Cave's series of cases, twenty-four out of the forty-two patients gave no history of encephalitis. Six of his cases were definitely post-encephalitic, and in twelve of them there was a history of influenza on an average of five years previous to the onset of the narcoleptic symptoms. It would seem, however, that narcolepsy has become much more common since the influenzal epidemic of 1918. Adie²⁴ was of the opinion that the family and personal history of the patient revealed no factors of etiological importance after reviewing fifty cases in 1930. Cave was of the same opinion. Camp, however, thought that it must be regarded as a mental defect. Gelineau speaks of it as a rare neurosis. Purves-Stewart,¹⁴ Church and Peterson,¹⁵ and others have been of the opinion that narcolepsy is hysterical in nature. I believe that narcolepsy cannot be explained on a functional or hysterical basis.

In Camp's series the sexes were equally affected and the age of onset was from ten to fifty-one years. In Cave's series thirty-four cases were in males and eight in females, a proportion of about four males to one female. The age of onset in males varied from nine to forty-six years. The duration of symptoms in males before examination by Cave varied from six months to twenty-one years. The age of onset in females varied from eight to thirty-seven years.

In 1907, Camp was of the opinion

that genuine cases of narcolepsy were not common in the literature. Adie, in 1926, stated that narcolepsy cannot be considered a rare disease. Cave's paper shows rather conclusively that it is a relatively rare condition when only one case is found in every 8,610 patients who were examined at the Mayo Clinic.

Cave's etiologic classification follows:

Idiopathic	23
After encephalitis	5
After infections other than encephalitis	3
Associated with hypothalamic syndrome	4
Associated with sleep attacks only	7
Total	42

Narcolepsy is essentially a chronic disease but the duration of the symptoms is unknown. Cave mentions four cases in which the patients had had attacks of sleep for fifteen, twenty and twenty-three years. Adie states that complete permanent recovery has not been observed.

Cases which often have been confused with true narcolepsy are those of hysteria, epilepsy, encephalitis, hypnosis, brain tumors, cerebral and arterial sclerosis, hypothalamic lesions and the somnolent symptoms sometimes observed in obesity and in pregnant women.

The report on the two cases of narcolepsy examined and treated by me follows:

CASE REPORTS

Case 1. A white male single 34 years of age, was examined on November 15, 1928. His family history was not significant. He had had the ordinary diseases of childhood. When I first saw the patient his present complaint was that of sleeping spells. He had been well in every way until 1918 when

he was in the army and noticed that while drilling he would become very tired. As time went on he would fall over while drilling because of extreme weakness in his muscles. When he went in for mess at noon he would fall asleep and it was with the greatest difficulty that the sergeant could awaken him for afternoon duty. These sleeping spells increased in frequency and severity and his weak spells became more marked on exertion. He said that at times he would sink to the ground if he laughed or became excited. About two months after his trouble first started he was removed to a Government hospital where he was treated for a supposedly weak heart. At no time did he have any dyspnea or edema and he was not conscious of any heart trouble. As time progressed, he often fell asleep while eating, walking and driving a car. His general health remained very good. During the past few years this patient has carried on a gainful occupation as an insurance salesman but it has not been infrequently that he would fall asleep while talking to a client. He has had several automobile accidents lately as a result of falling asleep while driving and he said that it was not unusual for him to fall asleep while driving or walking home and to awaken when he was several blocks beyond his home. His sleeping spells will last for about half an hour and are usually preceded by a drooping of the eyelids and some dimness of vision. His narcoleptic sleep has been very deep and has been as common in the early part of the day as in the latter part. He has had very sordid and wild dreams shortly after going to sleep at night. He often thinks that snakes and mice are crawling about him and while asleep he will even pick mice from his body and insist that those near him take them from his hand. He resents being awakened from the dream state and claims he has been somewhat pugnacious. He often dreams that the telephone is ringing and gets up to answer it. Since the onset of his trouble he has been unable to sit through a movie without sleeping during most of the performance and of late it has been impossible for him to drive a car at night.

The sleeping spells as he calls them have continued to trouble him for several years.

Laughter, excitement, anger or any emotional stimulus will bring on a shaky spell and if he is not able to grasp something he will sink to the ground. He has purposely avoided playing billiards because of these spells. The loss of muscular tonus or weakness is of very short duration in his case.

The patient's general physical examination was essentially negative except that he was slightly overweight and appeared to be somewhat dull. His eyelids drooped slightly. He answered questions with dispatch and there was no evidence of any neurotic tendency. He seemed to be ambitious and was very anxious to carry on his work. His blood pressure was systolic 140, diastolic 80, pulse 72, temperature 98.6°. The pupils were regular and reacted to light and accommodation. He has a small adenoma of the thyroid. His heart was normal in size, regular and the heart beats were of good volume. Examination of the lungs was negative. Abdominal and rectal examinations were of no importance. Neurological examination was negative. The fundus examination revealed nothing of significance and x-rays of the skull were normal. The urinalysis showed the specific gravity to be 1022, an acid reaction, no albumin, and no sugar, casts or blood. His blood count showed a hemoglobin of 80 per cent with a red cell count of 4,000,000 and a leucocyte count of 7,000. His metabolic rate was minus twenty on one occasion and minus eighteen on another. A Wassermann reaction was negative.

A diagnosis of idiopathic narcolepsy was made and the following treatment was instituted when the patient was first seen by me in 1928. He was given desiccated thyroid, grains 1 to 2, t i d, large amounts of coffee, and caffeine citrate, grains 15 to 2, t i d. He received absolutely no benefit from this treatment. Midway rest periods and sleep were tried and he would feel somewhat refreshed after these naps but for a short time only. As a matter of fact, the patient's symptoms have remained practically the same and his general health has not been impaired in any way since I first saw him in 1928.

In November, 1930, following the suggestion of J. B. Doyle of the Mayo Clinic, I started to use ephedrine for this disease

entirely. At the beginning of this treatment this patient's blood pressure, weight, blood count, urinalysis, fundus examination and neurological check-up were essentially the same as when I first examined him in 1928. His metabolic rate was minus seven which was somewhat higher than the previous tests.

This patient was given 0.375 grain (0.025 gm) of ephedrine on November tenth at five in the afternoon and 0.375 grain (0.025 gm) at eight the following morning, at noon, and at four in the afternoon each day thereafter. Following his initial dose of the drug he drove his car for one hundred and fifty miles on a hunting trip against the wishes of some of his close friends who were afraid that he would fall asleep and swerve the car into the ditch. He stated that he did not have the slightest desire to sleep and was much more awake than anyone else in the party. He had not been able to drive a car at night for several years. He hunted all of the next day, walked a great deal, but had no sleepy or weak spells. He returned home on the following day and spent the morning working on his car, had his noonday lunch, read in the afternoon and attended a "movie" that night. He had no desire to sleep during the "movie".

This patient has continued to be symptom-free from both his narcoleptic and cataleptic spells. It is interesting to note that several days after he started the ephedrine he was required to drive to a nearby town about sixty miles distant. As he left the house he picked up a box which he supposed contained his medicine. When it was time for the noonday dose of ephedrine he opened the box and found that he had brought the wrong medicine along. He attempted to purchase some ephedrine but it could not be obtained. As a result he was forced to go without his medicine until he returned home that night. He got along fairly well in the early afternoon but stated that he had to pull off the road several times on the way home to sleep for ten or fifteen minutes. He has played billiards without any trouble and says that his night sleep has been much more restful and that he does not have horrible dreams as before.

I still have this patient under observation and it has been necessary to increase the

dosage of ephedrine from 0.375 gr (0.025 gm) three times a day to 0.75 gr (0.05 gm) three times a day in order to keep the patient symptom-free.

Case II Is that of a boy, 13 years of age, who is perhaps overdeveloped mentally and physically for his age. He reported for examination on November 13, 1930, complaining of sleeping spells since the age of eleven years. These attacks were first noticed while he was riding in an automobile. As time progressed, he would fall asleep while in school or while eating. The spell would last for fifteen minutes to half an hour and he would be somewhat refreshed when he awakened. His night sleep was restless, he had sordid dreams and it was not unusual for him to get out of bed and walk about. His parents noticed that the weak spells in which he would fall to the ground were associated with laughter and exertion. After a few seconds or a minute he would be able to get up and would then be apparently normal. He tired easily and could not keep pace with other children of his own age in active play. He got along very well in school and was a leader in his class. His holidays were spent in sleeping for the most part and it was necessary for him to have an hour's sleep at noon each day in order to carry on his school work in the afternoon. It was not difficult to awaken him from his narcoleptic attacks.

The boy's family and personal history was negative. On general examination nothing significant was noted except that he was slightly obese and rather mature both mentally and physically. Basal metabolic reading was minus twenty when taken on two different occasions. His blood count and urinalysis were negative. His blood pressure was 100/80, pulse 72, temperature normal. Neurological examination was negative. The x-ray examination of his skull was negative.

I started treating this patient with ephedrine and he was given 0.375 gram (0.025 gm) of the drug at 7:45 A. M. the same dosage at noon and at 4 P. M. He was greatly relieved of his symptoms but continued to have occasional sleeping spells while riding in a car. He was able to enjoy a good joke and to play a game of football without having an attack or cataplexy. I

increased the dosage of ephedrine to 0.75 gram (0.05 gm) in the morning and at noon, and to 0.375 gram (0.025 gm) at four in the afternoon. He felt even better under this increased dosage but had one or two attacks of narcolepsy while in his manual training class in school and also fell asleep for a very short interval while reading. The medication was then increased to 0.75 grains (0.05 gm) three times daily. He now feels very well, is much more active, his night sleep is more restful, he is entirely free from the cataleptic attacks, and his parents say that they have noticed a remarkable change in the boy. He has had one or two short sleeping attacks.

The symptomatic treatment of narcolepsy has been without results until Daniel's¹¹ and Doyle's¹² recent report in which they suggest the use of ephedrine. Camp⁷ in 1907, Adie⁸ in 1926, Brock¹⁰ in 1928, Pearce¹⁷ in 1928, Cave¹⁰ in 1929, Common¹⁸ in 1929, Levin¹⁹ in 1929, Denyer²⁰ in 1930, and Ziegler²¹ in 1930, all of whom have reported cases of narcolepsy, are agreed that the different forms of treatment which they have used have not been effective. These included desiccated thyroid, caffeine citrate, liquid strychnine, hormone pituitary gland, sedatives, deep roentgen-ray therapy, and regular intervals of rest in bed, the two latter measures having afforded slight relief.

To gain the best results in the treatment of narcolepsy, ephedrine should be given orally in doses ranging from 0.375 gram (0.025 gm) to 0.75 gram (0.05 gm) three times daily. The first dose is best given at eight o'clock in the morning, the second at noon and the last at four in the afternoon. The last dosage is given early because Doyle has found that in some instances when the dosage has been given later in the day it has proved too stimulating.

and the patient has complained of insomnia and restlessness. It has been my experience in the cases that I have treated that the night sleep has been much more restful since the patient has been taking ephedrine and that my patients have been practically free from the morbid dreams that are so frequently a part of the narcoleptic syndrome. I think that it is perhaps most advisable to start these patients on an initial dose of 0.375 grain (0.025 gm) three times daily, and then to gradually increase to 0.75 grain (0.05 gm) three times daily, if necessary. Doyle increased the dosage in one of his cases as high as 1.125 grain (0.73 gm) three times daily, but the dose proved too stimulating for the patient. It appears to be very easy to establish the minimal dosage within a short period of time. There is the possibility that a slightly increased dosage of ephedrine may be required from time to time in these cases. So far as we know, there is no deleterious effect from the use of ephedrine in the amounts mentioned above.

Doyle says that "Chen and Schmidt,²² and Johnston²³ commented on the occurrence of sleeplessness in certain persons following the use of ephedrine. More recently it has become common knowledge that ephedrine tends to abolish the narcotic effect of sodium iso-amylethyl barbiturate (sodium amytal) and that as an antidote to morphine it is more valuable than caffeine."

I feel that Doyle and Daniels deserve great credit for suggesting an apparently successful symptomatic treatment for the symptom complex known as narcolepsy for which, up to

the present time, the medical profession has had nothing whatever to offer.

I believe that more time will be required to observe these patients who have been treated with ephedrine before final conclusions can be reached but so far the results in most instances have been remarkable.

Typhus-Like (Spotted) Fever from Tick-Bite*

Rocky Mountain Spotted Fever Type; Identified with a Symbiont Proteus-like Septicemia

By NOXON TOOMEY, B A , M D , F A.C P , *Palmyra, Mo*

CONSIDERING their world wide spread, and the toll of life they take annually, the typhus and typhus-like fevers are foremost among the grave fevers about which there is, at present, very little established concerning their microbic origin¹⁶⁷ Consequently, specific therapy for these malignant fevers, so very urgently needed, has remained, and will perhaps continue to remain, contingent for its development upon discovery of more complete and exact facts concerning their microbic origin Therefore, any data, even the least, should be made known in order that the typhus group of diseases may be placed on as complete and as scientific a foundation as the enteroida group of fevers

Although Rocky Mountain spotted fever has been demonstrated to be a different disease from typhus fever, it should be classed in the typhus group of fevers According to observations by Spencer there is a febrile disease clinically indistinguishable from spotted fever of the Rocky Mountains but caused by a tick-borne virus that is not the virus of Rocky Mountain spotted fever¹⁶⁶ Hence a sporadic case, al-

though clinically indistinguishable from spotted fever of the Rocky Mountains, if originating remotely from an endemic area, and without obvious contact with ticks imported from an infected area, should be classed as a typhus-like fever from tick-bite of Rocky Mountain spotted fever *type* until such time as the virus causing the sporadic case can be positively identified to be that of spotted fever of the Rocky Mountains This identification in our present knowledge can be made only from the patient's fresh blood (drawn during the fastigium of the disease), inoculated into guinea-pigs known to be susceptible to spotted fever, and into others known to be immune to spotted fever As differential immunity tests have not been made with the virus of this case, the case will for the present be referred to as of Rocky Mountain spotted fever *type*, although clinically a typical case of that disease

The purpose of this paper is to describe for the first time a case of Rocky Mountain spotted fever type originating in Missouri, midway between the original endemic area and the recently discovered eastern-southeastern states area,²¹⁷ secondly, to describe for the first time the clinical pathology of the

*Received for publication, July 31, 1931

spinal fluid in a spotted fever, and thirdly, to call attention for the first time to a virus pathogenic for man and maintained in nature probably as an antagonistic symbiont of a proteus-like microorganism.

A bacteriological and immunological study of this case has been prepared as a separate report.

CASE REPORT

Unexpectedly, and under circumstances that made a complete bedside study out of the question, I was called upon to render medical care to a woman who was found, in time, to have a disease which I never would have supposed could come for observation within the locality in which I practice. Although the uncontrollable restrictions of time and the distant location of the patient's residence, made it impossible for me to do certain laboratory work, and to repeat some bedside examinations as often as I would like to have done, the clinical and bacteriological data obtained are of sufficient value to warrant publishing, especially in connection with the recent discovery of Rocky Mountain spotted fever in eastern and south-eastern states, and the hitherto debatable observations concerning the nature of the virus causing spotted fever.^{110 161 162}

The patient's demise, although certified as due to Rocky Mountain spotted fever, should not be interpreted in such absolute terms, as actually the patient had an advanced heart lesion (double mitral—nodal arrhythmia) and died a cardiac death, although in mentioning this fact it is not intended to minimize the severity of the infection, which was gravely prostrating from its onset, and hyperpyrexial after the third day. It has been said that no one over the age of fifty has been known to survive the malignantly virulent form of spotted fever to which this case has closest resemblance.¹¹

Mrs. F. F., of Union Township, Marion County, Missouri, aged 69 years, 3 mos. housewife of naturally large and robust frame and musculature (known weight 166 lbs.), had resided on a farm practically all of her life and continuously so during the

latter half. She bore three healthy children (no miscarriages) by first marriage. Her second marriage was subsequent to menopause, which was without event. Inured to heavy manual labor up to four or five years ago.

Previous Medical History. Four or five years ago she began to develop an arthritis deformans that involved chiefly the hands and knees with moderate severity and other joints to lesser degree. She had not considered herself habitually constipated prior to four years ago but following a hemorrhoidectomy a year and a half ago whatever degree of constipation there may have been became worse, necessitating the use of a saline cathartic every few days.

Cardiac insufficiency, first noticed about two and one-half years ago became worse and remained so following a "typhopneumonia" about eighteen months ago. "Pneumonia" (in late autumn—diagnosed by osteopath) lasted acutely for four or five weeks, and with convalescence for four months, was said to have been of severe degree, with considerable emaciation (this illness has a bearing on recently finding her serum to agglutinate *B. typhosus* in dilution of 1:80, partial in 1:160).

The patient had otherwise been well except for one attack of acute frontal and ethmoidal sinusitis about ten months ago. Since then she was semi-invalided due to cardiac condition and rheumatoid arthritis but was nevertheless able to do most of her household and garden work the greater part of the time.

Present Illness History of Tick-bite. During the morning of May 29th, 1931, patient walked near wooded hills to inspect some flooded fields in a creek-bottom. Late on the same day a "small, red common wood-tick" was discovered on her right foot where it had engorged itself, about three centimeters proximal to the fourth metatarsal-phalangeal joint. The tick was removed and destroyed by a grain duster. She experienced no unusual hardships. The tick identified as a live *D. variabilis* in all respects distinguished from the tick that was removed. No other ticks were seen when the tick was removed. The tick was close to two per cent. engorged.

the evening of the day following as the site of the tick-bite was then itchy

Incubation Patient continued to feel well for seven and a half days, up to and including June 5, 1931, the afternoon of which day she made a trip to Palmyra, Mo., seven and a half miles distant, returning cheerful and without exceptional fatigue. Some vague malaise ("rheumatism getting worse") was perhaps noticed before retiring on June 5, although she slept the forepart of the night, but only brokenly and with restlessness during the latter part, which for her was quite unusual

Onset The following morning, June 6, Mrs. F. arose at 5 30 A. M. with a dull frontal headache, a pain in the left side of neck, and discomfort through her right hypochondriac region. She milked several cows but as malaise became rapidly worse and a sense of muscular weakness developed, with pronounced dull (deep drawing and boring) pains in extremities, particularly in biceps brachii, flexors of hands, hamstrings and crural muscles, she kept in bed from 6 30 to 8 30 A. M. but again got up and tried to do her housework. About 10 00 A. M. she took to bed with sudden profound chilliness (the day being warm). Chilliness was constant, exceedingly pronounced and was felt about equally over entire body, with absence of 'creepy feelings'. She probably did not have a true rigor but "no amount of bed-clothes and hot water bottles could get her warm". Chilliness continued unabated for four hours and then passed away slowly between 2 00 P. M. and 4 00 P. M. About 5 30 P. M. and again at 6 30 P. M. she vomited (a unique experience for her) and continued to feel nauseated for two hours thereafter. About 7 00 P. M. she had what was thought by relatives to be 'a heart attack' and I was sent for about 7 30 P. M.

Invasion (end of first day) I first saw patient at 8 30 P. M. at which time she answered questions readily, pertinently, coherently, and without retardation. Her temperature was then 102.4° F., pulse 112, respirations 22. Chief complaints were prostration (two days duration), pain in flexor muscles and vaguely in right diaphragmatic region. Slight cough (quite unusual to her) had developed during the latter part of the

day but there was no pain in chest or on deep inspiration, nor sense of thoracic constriction

Initial Physical Examination Eyes, ears, nose and throat were negative, she was edentulous and without struma. Chest was negative, abdomen was not distended nor tender to palpation. No cutaneous lesions except scabbed over tick-bite (to which no significance was attached). Cutaneous tache was without urticarial element but blanching with peripheral erythematization was exceedingly pronounced. Mobility of neck and reflexes were normal. Blood pressure systolic 155 (all beats at 150), diastolic, 108. Hemoglobin, 80 per cent. Heart murmurs were faint and inconclusive but were suggestive of double mitral lesion. Some nodal arrhythmia was present. Heart was transversely enlarged from 4 cm. left of left nipple line to 5 cm. to right of right sternal margin. Patient was slightly obese, tissue turgor was satisfactory.

Initial Impression and Therapy Temperature was tentatively ascribed to nasal sinusitis and subacute cholecystitis or enteritis following constipation and a dietary indiscretion, although a beginning pneumonia was considered possible (due partly to it then being said, somewhat erroneously, that she had had a 'typho-pneumonia' at the same time a year previously). Saline catharsis (effectual at 10 00 P. M.) and a hypnotic (sodium amytal, grains three, every four hours, if necessary) were prescribed, and tincture of digitalis (LaRoche) was commenced in dosage of 24 drops regularly every four hours.

Patient slept for one hour after first dose of sodium amytal but not after second dose, four hours later.

Second Day, June 7th During early morning, restlessness, fever (to 103° F.) and muscular pains having increased, I was called on by her son, and sent by him, sodium salicylate in raspberry elixir, grains twelve, every four hours, with instructions to take patient's temperature every three hours. Temperature continued absolutely constant at 103.2° F. during the second day without improvement in subjective symptoms. Patient coughed occasionally without difficulty, a little thin, clear mucus being

brought up. She cared for no nourishment but took orangeade and lemonade during afternoon without emesis. She slept not at all that night despite sodium amytal grains three every three hours.

Third Day, June 8th Early in the morning I was called to the farm immediately following a sudden change for the worse observed about 6:30 A. M., or about 48 hours after onset of the disease. I found patient stuporous although arousable, but unable to articulate answers to questions which she seemed to understand, and wished to answer to priest and myself. On command she could not protrude her tongue. At that time temperature was 103.6° F., pulse 98, respirations 24. Leucocyte count was 11,000. Fluids, no longer taken through glass tube, had to be fed to her with a spoon, but were swallowed with some slight difficulty.

Description of Skin Lesion At that time, 7:30 A. M., patient was observed to have over her lower limbs, flanks, and forearms (including wrists and backs of hands) a rash of medium profuseness, stated by relatives to have been first observed by them about 5:30 A. M., which would have placed its appearance about 48 hours after onset of the disease. When first observed by me on lower limbs and forearms there was over abdomen, chest and back an evanescent marmoraceousness which before long gave place to pinhead sized macules of dull ham (tawney) color that in a few minutes increased in size and remained permanently. After an hour or so the lesions became progressively more cyanotic or mulberry colored as they increased in size.

Skin lesions were mostly discreet oval or ovoid, split pea to lentil sized, compressible (to fawn color through diascopy) and non-indurated macules, for most part being not raised or only slightly raised above skin level. The macules, irregularly distributed and very slightly morbilliform had their long axes paralleling the cleavage lines of the skin. The color became a dull mulberry red at times but usually was more cyanotic (violaceous) and never was as intense and as red as in meningococcus meningitis. For brief periods the rash lightened to a faint cyanotic hue but never disappeared entirely.

The rash spread upward over abdomen, chest and back during the course of the morning and new lesions appeared on the extremities but the neck and face were at all times spared except for a dusky blush over forehead. The face was then a little puffed and had a lemon tinge over malar eminences but no icterus was visible in the conjunctivae.

The conjunctivae were then very pronouncedly injected, and remained so throughout the third day, but lachrymation was not present. Photophobia pretty certainly was present but on account of the woman's stupor it was not an outstanding symptom. The tongue was moist, a trifle swollen and lightly covered with a white coat down the center. The pharynx was spottily injected and the patient continued to cough at intervals of a half hour or so, but no macular lesions were observed on the palate or buccal surfaces.

As patient had not voided for over twelve hours, and apparently could not do so she was catheterized every twelve hours 800 cc being drawn off the first time but the subsequent amounts diminishing by about one hundred cc each time. The results of urine analysis and other laboratory work will be described following history.

Although patient was always a trifle cyanotic, her chest continued without evidence of pleurisy or pulmonary consolidation which with the low white count, stupor and spotted eruption, made me wish to exclude cerebro-spinal meningitis, despite the then well marked clinical picture of typhus fever.

The temperature curve, which from the first had continuously risen without a remission of more than 0.2° F. to a plateau of 103.6° during first half of third day, rose to 104° (axillary) during the afternoon (104.2° in early evening) of the third day, despite more or less constant cool sponging on upper two-thirds of body. Temperature (taken since morning by axilla) was charted at hourly intervals and showed a drop of 102° at 11 P. M. towards close of third day but during night rose to 104° at 5 A. M.

Medication during the third day consisted of tincture of digitalis increased to drops thirty-two every four hours, and a cathartic for mouth, upper intestinal and perirectal about twice per day, with a large

cylate in ten ounces of water given in teaspoonful drenches at five to ten minute intervals, patient then being no longer able to swallow without difficulty

When seen by me at 10 P M towards the end of the third day of disease, pulse was slower (84) and stronger, respirations 22, regular, of good excursion and without difficulty but with faintly audible inspiratory and expiratory wheeze. The patient was still coughing occasionally, but less frequently, chest negative for areas of consolidation (including posterior bases). Temperature 103.6° dropped to 102.2° an hour later, as mentioned above

A daughter residing at a remote distance, who arrived at 7 00 P M was unquestionably recognized by patient who could not, however, be aroused from stupor easily, nor kept aroused for more than fifteen seconds at a time. Occasionally the patient tried to give expression to some discomfort in lower extremities but was unable to make coherent sounds or gestures, or to turn herself in bed. A coughing spell caused patient to void a little urine, expel flatus and soil herself with a small amount of semi-solid feces (having previously done so about two hours before). Abdomen was neither scaphoid nor distended, flatus having been passed during coughing spells. Spleen was palpable, firm but not hard, and extended four fingers breadth below costal angle

Sodium amytal (about grains five floated on water) was later reported to have quieted patient a little during the third night

Fourth Day, June 9th, patient had a 'sinking spell' in early morning and I was summoned to house. At 8 A M temperature was 103.4° (axillary), pulse 82, respirations 22. Pulse was weak but regular. Oxygen with oxygen-carbon dioxid rebreathing revived heart action. Injection of conjunctivae was noticed to have passed away almost completely. Stupor was deeper, patient being not fully arousable, but no evidence of delirium. Flexion of neck restricted but not rigid; patient habitually rolled head to left side. She moved arms with apparent vague purposefulness but ineffectually. Cried out faintly as though in pain when moved, catheterized, and given bed care

The pulse having been revived, the morning was devoted to lumbar puncture, bedside laboratory work, and practically continuous cool sponging, the digitalis being continued

Telegraphic request for Rocky Mountain spotted fever vaccine was made to the Secretary of the Montana State Board of Health but Dr W F Coggsell promptly telegraphed back that vaccine was not used therapeutically

During the fourth day the skin became cool and clammy and the tissue turgor very much reduced. Cough abated and swallowing became almost impossible

Later Aspects of the Rash The rash during the fourth day became somewhat confluent in a few places on the back, buttocks, and lower lateral aspects of thorax, abdomen and hips, but nowhere did the blotches exceed an area of one by two centimeters. Interstitial (purpuric) hemorrhage to a grossly noticeable degree was observable in not over ten lesions, chiefly on the distal portions of the flexor surfaces of the extremities. Neither confluence nor purpura were, on the whole, striking characteristics of the rash

A few new lesions may have appeared during the fourth day but if they did so they did not attract notice

Not all of the lesions increased in size during the fourth day but after twenty-four to thirty-six hours from the appearance of the rash there was a larger proportion of lenticular and large lenticular lesions than during the day before, the spots being more distinctly visible at a distance, and permanently a more livid blue. Towards the latter part of the fourth day most of the macules were slightly sunk below the general level of the skin, and most of them (except in dependent portions) towards the end of the day took on an ashen blue, 'washed out' appearance

When patient was seen by me at 10 00 P M the pulse was found to be 136 and thready, the temperature having fallen to 102.6° . The patient was breathing without much difficulty, rate 24, but tracheal rattle was present. Venipuncture was attempted but only 16 cc of blood was obtained due to collapsed condition of veins. During the

night the pulse became imperceptible and patient expired at 7 20 A M on the morning of the fifth day, or about ninety-six hours after onset of definite symptoms of malaise, or about one hundred and eight hours from first prodromata

The temperature readings (axillary) of the last twenty-four hours were as follows: June 9, 6 00 A M, 103.4°, 6 35 A M, 103°, 10 00 A M, 103°, 11 30 A M, 103.6°, 2 35 P M, 103°, 3 30 P M, 104.4°, 5 10 P M, 105°, 5 40 P M, 104.4°, 6 25 P M, 104.2°, 7 00 P M, 103.8°, 8 10 P M, 104°, 9 00 P M, 103.8°, 10 00 P M, 102.6°, 11 00 P M, 102.8°, midnight, 102.8°, June 10, 1 30 A M, 103°, 2 15 A M, 103°, 3 00 A M, 103.4°, 4 00 A M, 104°, 5 00 A M, 104.8°, 6 00 A M, 104.8°, 7 00 A M, 103.6°, exitus at 7 20 A M

Laboratory Examinations

Blood White cell counts at 12 hrs after onset, 11,000, at 48 hours, 11,200, at 72 hours, 7,300 **White cell morphology** (72 hours) Cells took Wright's stain well, cytoplasm staining somewhat more intensely bluish than normal. Numerous polymorphs were quite large due to increased cytoplasm, and were somewhat ameboid in outline, but no polymorph or large mononuclear was found to have cell inclusions except rarely a few polar staining bacilli of Proteus type as described more fully in accompanying section on bacteriology. Although frequently it seemed as though the bacilli were in the leucocytes, in the majority of instances they were lying on the outside of the leucocytes

dilution of 1 80, partial in 1 160 (See history in regard to typhoid fever 18 months previously.) A typhoid agglutination made from partially dried, diluted serum drawn about the same time as that submitted to the National Institute of Health was reported negative by St Elizabeth's Hospital, Hannibal. Agglutination tests were made on blood drawn at the 88th hour of the disease.

Organisms Proteus-like organisms were first observed in the blood 48 hours after onset but no significance was attached to them as they were considered contaminations from the finger although the latter had been well washed with alcohol. Minute diplobacillary (and diplococcoid) organisms were observed in fresh and stained specimens of blood drawn 76 hours after onset, and a few proteus-like organisms were also observed as on the preceding day. Similar organisms having been found at the same time in the spinal fluid (microscopically free from more than a very occasional isolated red blood cell) some attention was paid to looking for granules and motile organisms but none were accepted as being motile (Brownian movement being taken into consideration) during the few minutes then at my disposal for such examination. Subsequent experience has convinced me, however, that there were minute motile (bacillary and diplobacillary) organisms then present. More numerous diplococci were found then than on the previous occasion.

Blood drawn under the most rigid aseptic precautions at the 88th hour of disease (10 hours before death) was sealed in sterile

Differential counts	Baso	Eos	Jung	Stabs	Segments	Lymph	L. Mono
at 48 hrs after onset	0	0	3%	7%	61%	20%	9%
at 76 hrs after onset	0	0	5%	8%	56%	20%	11%

Red cell counts at 7th hour 4 100 000. Color index 1. **Hemoglobin** 80 per cent (Talquist). **Clotting time** (needle drag method) at 48th hour, 275 min, at 76th hour, 45 min, at 88th hour 825 min, with serum deeply tinged with hemoglobin.

Agglutination tests (National Institute of Health—letter of June 15 1931 by R. E. Dyer) Agglutination of *B. proteus* A₁ positive in dilution of 1 20 partial in 1 40. Agglutination of *B. typhosus* positive in

tubes (kept at room temperature about 62 F) and examined fourteen hours later, at which time the blood was found to harbor mature motile proteus-like organisms and numerous minute diplobacilli (proteus-like) organisms as well as diplococci and retractile granules. The latter were of all sizes due to the diplococci being bacilli although some granules were observed adherent to the cells. However, as they were not motile they were not accepted.

refractile it was not clear whether they were monococcic forms of the diplococci or the granules associated with the latter. The mature proteus-like organisms were too motile to determine whether any granules were adherent to them, but a close study of stained blood smears indicated that these granular bodies must unquestionably have been within their surface tension area when they were motile. At that time I was not familiar with the work of Ricketts, Wolbach, Cowdry, Nagayo and others, and was disposed to regard the granules as "blood dust" and the proteus-like organisms as a terminal invader. However, subsequent studies, forming the basis of a bacteriological report to be made shortly, have convinced me that the "granules" in all probability constitute the virus of Rocky Mountain spotted fever.

Erythrocyte Morphology Unstained thick whole, thin whole, dry films, and unstained moist chamber films were examined as well as dried films stained with Giemsa's stain and with Wright's stain, Gram's stain, polychrome methylene blue, etc. Several hours search under the oil immersion ($\times 1100$) permitted drawing the conclusion that no organism could be found within the erythrocytes. The same basal (chromatin) staining, ultramicroscopic granules (monococci?) could be found in relation to the periphery of the red blood cells as mentioned above for the proteus-like organisms. In most instances the granules, which were a little angular in outline (wedge-shaped) appeared to be in contact with the surface of the erythrocytes, they were mostly nonmotile, but once a granule was seen to have a changing relation with respect to the erythrocyte, whether this was due to movement of a current in the moist chamber, or to motility originating in the granule, it was impossible to tell.

Stipple-celled degeneration, anisocytosis, poikilocytosis, fragmentation etc., were not observed up to the 88th hour. The sedimentation time was not observed.

Cerebrospinal Fluid Lumbar puncture (at 76th hour of disease). Small amount (6 cc) of fluid was obtained unmixed with the least macroscopic trace of blood. Spinal fluid was under no increased pressure and

came away only by drops at three or four second intervals. Crystal clear as drawn into sterile bottle and sealed.

Cell count, on blood counting chamber numerous fields were examined and averaged at 53 cells per c mm.

Reducing substance absent (0.5 cc used), boiled in three times the amount of Benedict's qualitative test solution. **Albumin** increased. Amount roughly estimated to be three or four times normal. **Globulin**, Pandy's test, not increased.

Red blood cells very occasional (under one to a field). Hemorrhagic encephalitis definitely excluded.

Organisms In fresh spinal fluid used for making the cell count a few proteus-like and di-coccoid organisms were observed under high power objective, but no diplobacilli. However, what attracted my attention were groups of exceedingly minute, barely visible, refractile granules too dispersed to constitute even a pseudo-morula, yet suggesting a community. The granules were not entirely scattered at random but all granules could not be associated with groups. When fresh cerebrospinal fluid was examined under the oil immersion ($\times 1100$) these granules were found to vary in size by about 100 per cent in diameter from smallest to largest, the largest being less than half the diameter of the di-coccoid (or diplococcoid) phase of the proteus-like organism. The granules were not mobile nor was there noticeable movement of or within the colony, which resembled the appearance of a constellation of stars on a bright night.

Fresh cerebrospinal fluid concentrated somewhat by low heat on a bacteriologically clean slide and stained by Wright's and by Giemsa's stain showed numerous mature proteus-like organisms, with polar staining well marked, rickettsia forms in chains of twos and threes, and what appeared to be masses of granular detritus around them. As the latter took the chromatin (polar) staining as well as the polar and band-like masses in the mature proteus-like organisms, the granules were presumed to be bacterial extrusions or nuclear fractions of disintegrated proteus-like organisms. The granules were not pin-point round but had a variable three-cornered rounded angularness or wedge

shape. No micrometer measurements could be made at the time, but the largest granules were estimated not to exceed 0.12 micron in largest diameter.

Urine. Catheterized specimen at 48 hours after onset (12 hr A. M. specimen). Amount, 800 cc. Color, deep amber, colloidal cloudiness becoming flocculent. No bacterial haze, no bile. Sp. gr., 1.022. Reaction acid to litmus. Albumin, large trace. Sugar absent. Microscopically free from pus cells and crystals. Some epithelial cells from bladder.

Catheterized specimen at 72 hours after onset (12 hr A. M. specimen). Amount, 600 cc. Color, dark amber, colloidal cloudiness becoming flocculent. Suggestion of bacterial haze. No bile. Sp. gr. 1.030. Reaction, markedly acid to litmus. Albumin, very small amount. Sugar absent. Microscopically free from pus cells and crystals, epithelial cells from bladder more numerous than on preceding examination. Occasional red blood cells. Numerous motile bacilli now seen for first time, type not identified.

Animal Inoculation

Blood drawn at the 88th hour of the disease and kept sealed in a sterile container at room temperature (62° F.) was injected 22 hrs later into a female guinea-pig. The injection was made at St. Elizabeth's Hospital, Hannibal, Mo., at 8:30 P. M. on June 10, 1931. With sterile syringe 1 cc of patient's (imperfectly clotted) blood was drawn into 2 cc of sterile water and mixed in the syringe and then injected intraperitoneally into a guinea-pig weighing about 220 gms. Only 2.4 cc (0.66 cc of blood) was injected due to plugging of needle. The guinea-pig was found dead about eleven hours later.

When necropsied twelve hours later the guinea-pig was found to have a markedly swollen, erythematous vulva and hemorrhagic foci in all foot-pads of three feet but no cutaneous lesions. The puncture had done no injury to the intestines or to a large blood vessel, and there was no evidence of peritonitis. Several areas of thickly studded 'pin-point granulations' on the parietal and visceral peritoneum were noticed but not at that time realized to be a manifestation of fatal spotted fever in the guinea-pig.

From the small amount of thin, sanguinous fluid in the peritoneal cavity, smears were made and stained with Wright's stain. The smears showed only very occasional proteus-like organisms that took the stain very poorly. It seemed, therefore, likely that these organisms did not proliferate in the guinea-pig, and were not the cause of death.

DIAGNOSIS

Apart from virus studies of this case, preliminarily reported above, the differential clinical study should take into account typhus fever, meningococcus meningitis, typhoid and the paratyphoid fevers, a streptococcus septicemia and spotted fever of the Rocky Mountains. If the fever had been contracted in certain other localities it would be necessary to consider the septicemic type of plague, to say nothing of certain Asiatic and tropical fevers.

The meningococcic and pneumococcic meningitides can be unequivocally excluded by the clear spinal fluid, not under pressure, and the absence of the characteristic and easily recognizable organisms of those diseases.

Typhus fever can not be excluded on clinical evidence alone. Indeed typhus was given serious consideration about the forty-eighth hour after onset, and it was only the history of tick-bite, the more abrupt and quicker more malignant clinical course and profuse lenticular macules (larger and more evanescent than usually occur in typhus) that decided in favor of Rocky Mountain spotted fever. In this connection it is to be noted that *Proteus* V₁ was agglutinated in dilutions of 1:20 and partially in 1:40, but thus the Weil-Felix reaction is known to occur in Rocky Mountain spotted fever.^{22, 23}

Streptococcic septicemias of malignant character have occurred in my practice and have, of course, been noted to cause petechial eruptions, but the febrile course has always been very irregularly remittent (septic type) and the peliosis has been hemorrhagic (purpuric) from the instant of first appearance, especially never fading under the diascop. Besides, the petechiae come out only in small numbers at a time, at random, the face and neck not being spared and the spread of the eruption is not rapid and orderly like an exanthem, as in spotted fever.

Typhoid fever with typhus-like course occurs occasionally and a case of such sort could not be unequivocally excluded by clinical appearance alone. Also is to be noted that the patient's serum was reported to have agglutinated *B. typhosus* in dilution of 1:80 (partial in 1:160) although by one observer it was reported negative in blood drawn at same time as that from which the quasipositive report was obtained. In this connection is to be observed that the patient probably had a case of typhoid fever about eighteen months previously. The rapid pulse, moist anemic, swollen tongue, firm spleen, absence of abdominal distention and urine without a well marked bacterial haze were not conformable to typhoid fever in even an early phase.

Over and above the history of tick-bite, and the virus (with a rickettsia-like phase) obtained from the blood and spinal fluid, the character of onset, steadily rising unremitting fever, very pronounced injection of the conjunctivae without lacrimation, and the typical muscle pains associated with the type of eruption would be sufficient to

establish a clinical diagnosis of Rocky Mountain spotted fever.

For the history, symptomatology and clinical types of Rocky Mountain spotted fever see the author's paper "Mountain Fever and Spotted Fever of the Rocky Mountains—Clinical Studies"

BRIEF CORRELATION WITH PREVIOUS INVESTIGATIONS

Spotted fever of the Rocky Mountains was first described clinically in 1896.¹ Clinical differences between the virulent form in the Bitter Root Valley and the more benign form in Idaho were described between 1898 and 1902.^{2,3,9,14} An intermittent form, very probably however a separate disease, was described by Kieffer in 1907.³⁵

Wilson and Chowning focussed attention on the transmission by a tick,⁶ but mistook artifacts for proplasmids.²⁷ Anderson supported the tick theory and found in the blood, during the disease, diplococcoid organisms that resembled forms encountered by me.¹¹ Stiles, who had attacked the tick theory in 1905,²² described the common vector, *Deimacentor andersoni*, in 1908.⁴² McCalla and Biererton in 1905 transmitted the disease by tick-bite to man,⁴⁷ and in 1906 King²⁴ and Ricketts²⁹ transmitted the disease by tick-bite to guinea-pigs.

Chowning in 1908⁵⁴ described, as the cause of the disease, but on inconclusive evidence, a proteus-like organism similar to the one recovered by me and shown by me to be non-pathogenic.

Ricketts succeeded in maintaining the virus in the guinea-pig²⁵ and showed that it was non-filterable,³² later confirmed by Spencer and

Parker¹⁴⁵ Ricketts incriminated minute, uncultivable diplobacilli (rickettsiae) which he found were transmitted from one tick generation to the next through the eggs⁵⁵ Moore in 1911 showed that the tick did not infect at once but required 175 hours to infect a guinea-pig and that it required about ten hours of feeding for a tick to acquire infectiousness from a guinea-pig⁷¹ Maver showed that ticks other than *D andersoni* could transmit the disease⁷³

In 1907 wild rodents, which had been suspected as being the natural reservoir of the disease were found to be susceptible to it³³ Studies by McClintic, who lost his life in investigation of this disease, had to do chiefly with the disease in nature and the institution of control measures by clearing underbrush, destroying small wild life, etc⁷⁹

Bacteriological work done by Mitche and Parsons in 1916 showed that the virus could not be recovered by the cultural means then available⁹⁶

On presumptive but very equivocal evidence, Wolbach in 1918 described Rickett's diplobacilli as the virus¹⁰² and obtained some growth of these rickettsiae in tissue cultures¹²⁷ Noguchi later failed to isolate a virulent rickettsia from known infected ticks but did show that three strains of rickettsiae from such ticks were not pathogenic,¹⁰¹ whereas a filter-passing virus could be obtained from *D andersoni*¹⁰²

The most significant recent developments have been the demonstration of the spread of the disease in the Rocky Mountain and adjacent states,¹²⁷⁻²⁰⁰ the development by Spencer and Parker of a practical vaccine from

ground-up infected ticks^{153 109} and their studies of the virus^{145,197} Spencer and Parker showed that the virus has a latent, immunity producing phase and that to acquire virulence it requires reactivation, which occurs during the process of engorgement of the tick¹³⁰ They also showed that the virus was not thrown down by high speed (8800 R P M) centrifugalization, and that it could not be separated from the red corpuscles and white blood cells by repeated washings¹⁵⁵

The most important recent developments have been the discovery of transmission in nature by means of the rabbit-tick,¹³¹ the introduction of tick parasites,¹⁵³ the further demonstration of the utility of the Spencer-Parker vaccine,²⁰⁹ and the demonstration of the disease in an eastern and southeastern states endemic area by L. F. Badger, R. E. Dyer and A. Rumreich^{210 217}

Post-Pneumonic Lung Abscess Resembling Lung Tumor*

With Case Report

By GEORGE F. COOPER, M.D., Lieutenant, Medical Corps,
United States Navy, *Cenacoe, P. I.*

IT IS difficult to differentiate an unresolved pneumonia from an encapsulated empyema in which the retained fluid is under pressure. It is also difficult, at times, to differentiate either of the two conditions mentioned above from a lung tumor. It is usually necessary to take into consideration not only the physical findings and x-ray examination, but the history of onset before an absolute diagnosis can be made.

Middle lobe pneumonia, without involvement of the remainder of the lung, is a rare condition,¹ and may terminate in various ways. It may resolve and clear up in a very short time, or it may go on to suppuration and gangrene. The condition may also break down into abscess formation and this collection of pus be later evacuated into a bronchus and drained. The case reported is believed to be one of the latter type.

It is an unusual case and was variously diagnosed as malignancy, encapsulated empyema, lung abscess, and finally a resolving pneumonia.

Figure 1 shows the first x-ray taken before the pus was evacuated. The

density of the shadow very closely resembles that of a lung tumor. At that time percussion over the area gave a total dullness. Breath signs were entirely absent. During the night the patient had a series of severe coughing spells and began to expectorate large quantities of a purulent greenish pus which was without the odor usually associated with lung abscess.

The next morning the area was aspirated and nothing could be withdrawn. Another x-ray was taken (figure 2), and it was found that the area in the right lung had changed slightly in density and outline. The top border appeared flattened rather than dome-shape. The patient was then allowed to rest for a few days.

At this time breath sounds were beginning to reappear over the mass, and a third x-ray (figure 3), was made. This latter suggested a resolving pneumonia, with a suggestive area in the center of the mass which resembled cavity formation.

The patient continued to cough up quantities of purulent material for several days, but this gradually decreased in amount and finally disappeared.

During the night in which he first

began to expectorate pus from the lung, his temperature was 103.8° F, but this dropped to 97.6° F, by morning and has been normal since. His leukocytes at that time were 14,600 with 64 per cent polymorphonuclears. Pulse at no time had gone over 100 since day of admission to hospital and respirations had been normal at all times.

Since this patient gave a history of illness with pain in left chest for three months, it is believed that he had a pneumonia at one time which left a collection of pus either in the middle lobe of the right lung, or an encapsulated empyema between the upper and middle lobes.

While the x-ray in figure 1 resembled a pneumonia, the pulse, respiration and leukocyte count were all against such a diagnosis. The mass was sharply outlined and the dullness on percussion such that a diagnosis of malignant tumor seemed justified. The patient's general condition was not good, and he gave a history of having lost considerable weight over a period of three months.

His most constant symptom during that three months was pain. This was

FIG 1 First x-ray taken on January 20 1931

FIG 2 X-ray taken on January 27, 1931, showing slight decrease in density and size of area

so severe that he walked in a bent over position. He had no difficulty in breathing and stated that he noted no fever at any time. He was not coughing at time of onset and had no coughs or colds previously.

Sputum examinations have been consistently negative for acid fast bacilli, the only abnormal finding being many pus cells and two organisms in abundance, one of which resembled *B. influenzae*, and the other a short chain streptococcus. Pneumococci were noted once.

Immediately after expectoration from the lung began to increase, the pain in his chest became less, the patient felt better, began to gain in weight and in a few days was symptom-free. The illustrations are from x-rays taken at different intervals as mentioned and show his condition at the different stages of his illness. The case history and laboratory findings are given in detail below. Chart 1 shows the temperature, pulse, and respiration with the drop in temperature during the night of the twenty-third when the abscess began to expectorate.

FIG 3 X-ray taken on February 6th, 1931, showing considerable decrease in size and density of area in lung, with a suggestion of cavity formation

CASE REPORT

January 19, 1931 P A B, a white male, age 33, well developed and fairly well nourished, admitted to medical ward complaining of severe pain in right side of chest, which he states has been present for three months

Past History This is the third attack of the same condition in the past three months. Has had a continuous temperature with night sweats and coughing in the early morning. Contracted syphilis in 1926, but has had adequate treatment

Family History Father dead at 62, heart disease. Mother dead, cause unknown. Two brothers and one sister living and well. No history of cancer, insanity, or tuberculosis in the family

Physical Examination Eyes, ears, nose and throat negative. Heart negative. Lungs: Coarse râles over areas of both lungs, and areas in right lung suggestive of small cavity formation. Patient is suffering from considerable pain in his chest at present, especially when he coughs. There is an area of dulness over the entire middle lobe, right lung. Examination otherwise negative

X-ray of chest, shows a mass which occupies practically one-half of the right lung (figure 1). While this patient has had syphilis, it is not believed that the condition in his lung is a luetic infection. Kahn test is negative and has been for the past year

Laboratory Data Leukocyte count 11,300, neutrophils, 64%. Red blood count, 3,900,000. Hemoglobin, 70%. Urinalysis negative. Kahn test negative. Sputum negative for acid fast bacilli on several occasions, but shows a few gram-positive diplococci, many short chain streptococci, and an abundance of small bacilli, morphologically resembling *B. influenzae*

January 22, 1931 Leukocytes 14,600. Polymorphonuclears, 66%

January 24, 1931 Patient had a severe coughing spell last night and began to expectorate copious amounts of purulent sputum. Temperature dropped during the night. Taken to surgical ward and lung aspirated, but no free pus obtained, probably on account of drainage during the night

January 25, 1931 Temperature has remained down and patient feels much better. Pain is less. Coughs considerable but it is a productive cough. His condition appears to be either a walled-off abscess occupying the entire middle lobe of the right lung, or a malignancy. The x-ray shadow under the fluoroscope is almost as dense as the heart shadow

January 25, 1931 X-ray of this date shows a suggestion of lessened density in the mass with a change in the outline at the top border. The lower border is ragged and appears to be attached to the diaphragm which is higher than normal on that side. Of course, the right side of the diaphragm is normally higher than the left, but this appears to be even more so, and under the

FIG 4 X-ray of chest made February 14, 1931, showing almost complete resolution

fluoroscope, to move with the mass in the lung

Stereoscopic plates show the condition to be very close to the chest wall anteriorly, and close to the surface of the lung

January 26, 1931 Temperature 98.8° F Has slight pain Cough is still productive of much purulent sputum The sputum has no odor as would be expected from a lung abscess Patient has no history of coughs, colds, or other illness prior to the onset of the present condition, the first symptom of which was pain in the chest, three months ago

January 27, 1931 Examination this date shows a lessened density of the area involved with increased breath sounds Mass does not seem so sharply outlined on percussion X-ray taken in standing position at 36 inch

distance shows a decreased density of the area with a beginning resolution in the center, which seems to be clearing up Top border has changed in appearance Instead of a convex border it is now concave Total area is noticeably decreased in size Patient continues to expectorate considerable purulent material Lung at this stage suggests a resolving pneumonia The part of the lung involved corresponds almost exactly with the outline of the middle lobe right lung

January 31, 1931 X-ray of chest shows decrease in density and size of area in right lung, with adhesions downward and towards the hilum

Further questioning of patient as to onset of illness reveals the following information

"At time of onset his bones ached and he

felt very weak. His chief complaint was pain even on pressure outside the ribs of his right side. The pain finally became unbearable and he turned in. At that time he had a cough, which was non-productive. He admits that on one occasion, one month prior to admission to hospital, he coughed up considerable pus and all symptoms were relieved for a while.

February 2, 1931. Percussion note is clear and practically the same all over the chest. Auscultation reveals signs of a large cavity with harsh breath sounds. The area over which dulness on percussion was elicited at admission now gives almost cavernous

breath sounds. The remainder of the chest is practically normal.

February 14, 1931. X-ray of chest (figure 4) shows almost complete resolution of the mass and is suggestive of a resolved pneumonia.

April 17, 1931. Guinea pig inoculated with pus from lung on January 27, 1931, is healthy and has gained in weight. Autopsy shows no signs of tuberculosis.

Modern Conception of Retinal Detachment with its Relation to Internal Medicine*

By CLYDE A. CLAPP, M.D., *Baltimore, Maryland*

IT MAY seem to you that the question of detachment of the retina is rather a special subject to bring before a group of internists but in recent years there has been a new conception as to the etiology of one type of this condition, and a new line of therapy has been developed. This new conception of etiology and therapy as well as our frequent call upon the internists for help in diagnosis of the cause of these conditions warrants our consideration of this subject.

As you all know the retina is very loosely attached to the underlying tissue and can with comparative ease be separated from it. Detachments from the etiological standpoint are usually grouped under four heads:

- (1) Those due to trauma,
- (2) Those in which the retina is pulled away from its attachment by bands of connective tissue in the vitreous,
- (3) Those in which the retina is pushed from its bed either because of a tumor or growth of the choroid or because of an extensive exudate,
- (4) Those in which no particular

cause can be determined, or the so-called idiopathic group.

Those cases which come under group 1, due to trauma, usually show marked improvement under rest and frequently entirely subside, leaving the retina fully attached and with normal fields of vision.

The cases in group 2, which are caused by contracting bands of fibrous tissue in the vitreous, usually follow a hemorrhage into the vitreous and the treatment is almost universally disappointing.

Group 3, consisting of those cases in which the retina is pushed from its bed is of very great interest. Especially is this true in those cases resulting from massive exudate from the choroid, a condition which occurs in acute toxemia of pregnancy or in acute nephritis not associated with pregnancy.

I will show you two examples of the former, one showing a large detachment above and below and the other showing a complete peripheral detachment. The ophthalmoscopic picture is most striking and when first observed the tendency is to give a very grave prognosis as to sight. One can, however, be very optimistic since practically all of these detachments subside as the general condition improves.

*Presented at the clinical session of the Baltimore Meeting of the American College of Physicians, March 24, 1931, at the Wilmer Clinic.

and the retina becomes fully re-attached. The detachments in acute nephritis have a similar appearance to those of toxemia of pregnancy and both have a tendency to change their appearance very rapidly. My experience has been that when detachments occur as a result of nephritis not associated with pregnancy, the prognosis as to life is very grave and the patient usually dies within a few weeks or months.

Another very small number found in this group are due to a tuberculoma occurring in the choroid, which may elevate the retina. The use of the graduated tuberculin skin test as an assistance in diagnosis is to be recommended and tuberculin therapy is indicated. In a few cases beneficial results are obtained from this line of therapy, although often the pathological process is so advanced that improvement fails to take place.

Group 4, which is by far the most numerous, consists of those detachments which occur spontaneously and which were formerly known as idiopathic. It is to this group that I especially desire to call your attention in view of the new conception in regard to the etiology, and the new treatment instituted. The explanation given by Leber and later adopted by Gonin, that usually there is a localized disease of the retina, with atrophy and at times cystic formation which finally tears, leaving a gap or rent through which the vitreous penetrates, separating the retina from the choroid and giving the

characteristic appearance, is the one widely held at the present time.

I have recently been fortunate in securing an eye which showed an old idiopathic detachment and I have had serial sections made in order to demonstrate, if possible, the presence or absence of such a rent. These sections show an old degenerated retina with marked cystic formation and at a short distance from the ora serrata there is a considerable rent in the retina through which the vitreous has penetrated thereby elevating the retina. This rent is comparatively small since ten sections upon either side shows a continuity of the retina. A similar rent also exists on the opposite side of the eye.

Gonin believed that the reason that results were not obtained in the treatment of these cases was that the opening in the retina allowed the vitreous to penetrate beneath the retina and this prevented its re-attachment. He therefore conceived the idea that if one could close these openings by searing their margins with the actual cautery, the retina would return to its bed. He first reported his results in 1919 and at the present time (July, 1930) claims that sixty per cent of these cases, if the detachment is recent, can be cured by this procedure. While American ophthalmic surgeons are not quite as optimistic as our European colleagues the procedure certainly offers more hope for restoration of vision than the old line of treatment of rest in bed for long periods, with hot packs and sweats.

How to Obtain More Autopsies*

By D SCHUYLER PULFORD, M D , F A C P , *Woodland, California*

THAT the percentage of autopsies obtained in any hospital or community is in direct proportion to the interest and efforts of the physicians in getting post mortems, is proven by numerous experiences. Some institutions and teaching hospitals have an average of eighty per cent, or more. In most city hospitals permits are exceedingly low, say from five per cent to twenty per cent.

Justifiable pride in ninety per cent autopsies obtained at the Woodland Clinic, for institutional deaths during 1930, and a belief that a discussion of the methods used in obtaining such a high percentage of necropsies will be of help to others, prompts the following report.

REPORTED PERCENTAGE OF PERMISSIONS

The Council on Medical Education and Hospitals of the American Medical Association¹ in its report of the essentials in a hospital approved for interns revised to January 1, 1930, states that "inasmuch as the percentage of autopsies has come to be recognized as an index of the educational activi-

ties in a hospital, no institution will be approved for the training of interns which does not have a record of autopsies of at least fifteen per cent." This requirement has not been changed to date.

This Council reported in 1927² after a survey of 538 representative hospitals in the United States, the following percentages of autopsies:

3 hospitals with autopsies from 90 to 100%
2 hospitals with autopsies from 80 to 90%
9 hospitals with autopsies from 70 to 80%
13 hospitals with autopsies from 60 to 70%
8 hospitals with autopsies from 50 to 60%
26 hospitals with autopsies from 40 to 50%
42 hospitals with autopsies from 30 to 40%
91 hospitals with autopsies from 20 to 30%
35 hospitals with autopsies from 15 to 20%
107 hospitals with autopsies from 10 to 15%
122 hospitals with autopsies from 5 to 10%
80 hospitals with autopsies from 1 to 5%
None recorded 0 to 1%

Percentages have probably improved since that date but they are still lamentably low compared to those obtained in foreign countries.

Henry A. Christian³ of Harvard Medical School states, "The number of necropsies obtained on patients dying in the hospital is perhaps the best single index of the professional efficiency of the hospital or the amount of work devoted to the study on patients by members of the staff or the eagerness of the staff to better their teaching ability."

*From the Department of Medicine and Pathology, Woodland Clinic Woodland California

Received for publication November 18 1931

Richards⁴ in 1921, reported that in St Luke's Hospital, New York City, one surgical service obtained forty-five per cent autopsies, and one ten per cent, and drew the conclusion that "success in obtaining necropsies depends upon the zeal and interest of the various staffs"

Doctor Bell,⁵ in 1928, reported a high percentage of autopsies in teaching institutions in Minneapolis and stated that "the most important factor in increasing the number of post mortems is to get the physician deeply interested"

Doctor Kingsford,⁶ in reviewing a year's autopsies in teaching institutions in Hanover New Hampshire, reported forty-five autopsies upon sixty-eight deaths, 66.2 per cent. He attributed a rather rapid increase in the number obtained in his institution to the factor of "merely asking permission"

Robertson,⁷ of Rochester, Minnesota, considers "percentage of permissions an index of the scientific spirit of any medical group" He also states that "when the clinical and laboratory staffs know that a serious effort will be made to get post mortem examinations and that they will be obtained in a large percentage of cases, the whole staff is stimulated to more careful work" And he feels that the patients

will thereby be cared for more safely

It seems probable that when hospital staffs become autopsy minded a minimum of 50 per cent autopsies should be obtained by all hospitals

AUTOPSY MATERIAL

Sixty of the sixty-six patients who died at the Woodland Clinic twelve hours or more after admission in 1930 were autopsied. Although as institutional deaths are usually accorded only those patients who die after being in the hospital forty-eight hours or more, we felt that after twelve hours sufficient contact and interest in the clinical course was established to necessitate a post mortem examination to correlate clinical and pathological findings. If we include five cases dying less than twelve hours after admission who were not autopsied, we have seventy-one deaths with sixty autopsies, or 84.5 per cent. Obstetrical service baby deaths are not figured in this report because autopsies were not sought on this service, most of the deaths being due to prematurity. There were some autopsies done on these babies but neither the deaths nor the autopsies are included in these statistics.

Of those deaths occurring less than twelve hours after admission there were two from cerebral hemorrhage.

TABLE 1

	Admissions to Hospital	Per Cent	Deaths	Autopsies	Per Cent Autopsies
Medical	844	17	44	35	79.54
Surgical	1259	55	27	25	92.59
Obstetrical	157	8			
Total	2260	100	71	60	84.5
Patients dying less than 12 hours after admission			5		
Institutional Deaths			66	60	90.90

THE COST OF AUTOPSIES

The idea that necropsies cost too much money for small hospitals to consider is refuted by our experience. Much benefit is derived from a necropsy even if not done by the best pathologist and even if a complete microscopic and bacteriologic study is not made. When performed in a large pathology section of a university or teaching hospital the expense is great because of the complete detail and thoroughness of the work. The expense of an autopsy in Mt Sinai Hospital in New York City in 1930, where four hundred and twenty-seven were done, was reported by Doctor Joseph Turner¹¹ to be ninety-two dollars each. Such a figure is not applicable to the smaller, less pretentious hospitals or clinic, nor is any such expense necessary. One should not imply from this statement that we advocate a poorer type of work. Until such expense can be met we would advise stimulating interest and increasing the percentage of necropsies until more money is available. This may in turn help to put in motion forces that will bring money for more detailed work. It might be helpful to call attention to the point where the expense of the Mt Sinai system, for example, need not be shouldered by the smaller hospital or group of physicians.

At Mt Sinai under the "Direct Charges" are listed

- (1) Pathologist's salary,
 - (2) Morgue space and overhead
 - (3) Morgue keeper,
 - (4) Supplies
- and under "Indirect Charges"
- (1) Time of staff interns and other attendant's expense in getting permission

- (2) Time consumed in the clinical preparation and presentation

The greatest expense is probably the direct charge to the pathologist's salary. In order to reduce this a part-time pathologist may be employed, or a competent pathologist in the vicinity may be paid by the hospital or group of doctors interested for each post mortem done. All the other fixed charges having to deal with the morgue can be eliminated by the full cooperation of the undertaker. Autopsies can be performed as satisfactorily in an undertaking parlor as anywhere else, and gloves, instruments and supplies are often supplied by the undertakers in exchange for the doctor's good will. As to the indirect charge to staff and clinical pathological conferences, this is not to be thought of on a charge basis in a small hospital or city, for the educational element and the added prestige and ability developed by the doctor more than repays each man for his time. As far as the hospital and public are concerned the small expenditure necessary is well worth while, for as Doctor Turner says it is "eventually returned to the contributing public with compound interest in the form of improved practice of medicine in the hands of better trained physicians."

SUMMARY

1. A practical inexpensive method of getting a high percentage of autopsies applicable to almost any community is outlined.

2. Not having a highly paid pathologist available is not a real obstacle.

3. Sixty of the sixty-six patients who died at the Woodland Clinic twelve hours or longer after admission

is modified by increased knowledge gained by postmortems (5) Aid in settling insurance claims. (6) That there is no delay and no extra charge (7) That the high average per cent of autopsies permitted in the past by all classes of people in the best institutions testifies to the procedure being reasonable and proper.

No such interest in obtaining permissions could be kept alive without a strong stimulus and this was delivered in the form of a bimonthly or monthly clinical pathologic conference, fitting their frequency to the amount of material available, and not to any set date. Since it was the custom to have a weekly staff meeting for magazine reviews, reports of meetings or papers in preparation or heard or read elsewhere, it but remained for the pathologist to request the necessary time to present the material available and ready at any routine weekly staff meeting.

It seems best to have the pathologist as leader to present the case history of all deaths. The stimulus needed to induce and maintain interest in the clinicians depends in a large part on the excellence of the pathologist. The case history of the patient who had no autopsy often served to emphasize how important autopsies are, so they were also presented. After discussion by all doctors who saw the patient, gross specimens were shown and then microscopic slides projected. Closing discussion brings out any mistakes in diagnosis, delays or omissions in treatment and remarks as to similar cases seen formerly or elsewhere. Such universal favorable comment has been received from staff members as well

as visiting physicians that it is planned to extend the clinical pathologic conference to include the material removed at the operating table together with the clinical reports of these surgical cases which present interesting tumors or situations.

Clinicians and pathologists alike admit their limitations and failures, for although death is, *per se*, admission of failure of the physician as treatment did not preserve life, yet often the pathologist, too, is at a loss to explain many causes of death, save by such unsatisfactory terms as surgical shock, toxemia, exhaustion, etc.

Those interested in developing logical and plausible points to convince relatives of the value of performing a postmortem should read Emil Bogen's article printed in *Hygeia*, December, 1926. Also a very good detailed article on, "Answers to Layman's Objections to Postmortems", is that of Doctor Ralph Mills,⁹ published in the *Bulletin of the American College of Surgeons*, of December, 1930. All pathologists and coroners should also familiarize themselves with Schultz's¹⁰ recent article, "The Law of the Dead Human Body".

To summarize, it appears to the writer that the four most important factors in obtaining autopsies, in the order of their significance are (1) obtaining one hundred per cent effort and interest on the part of the doctors concerned, (2) establishing a close personal understanding and trust and friendship between doctor and relatives during the patient's illness, (3) cooperation of the undertakers, (4) creating the proper public sentiment towards postmortems.

THE COST OF AUTOPSIES

The idea that necropsies cost too much money for small hospitals to consider is refuted by our experience. Much benefit is derived from a necropsy even if not done by the best pathologist and even if a complete microscopic and bacteriologic study is not made. When performed in a large pathology section of a university or teaching hospital the expense is great because of the complete detail and thoroughness of the work. The expense of an autopsy in Mt Sinai Hospital in New York City in 1930, where four hundred and twenty-seven were done, was reported by Doctor Joseph Turner¹¹ to be ninety-two dollars each. Such a figure is not applicable to the smaller, less pretentious hospitals or clinic, nor is any such expense necessary. One should not imply from this statement that we advocate a poorer type of work. Until such expense can be met we would advise stimulating interest and increasing the percentage of necropsies until more money is available. This may in turn help to put in motion forces that will bring money for more detailed work. It might be helpful to call attention to the point where the expense of the Mt Sinai system, for example, need not be shouldered by the smaller hospital or group of physicians.

At Mt Sinai under the "Direct Charges" are listed

- (1) Pathologist's salary,

Editorial

MOTTLED ENAMEL DUE TO FLUORIDE

In the condition known as mottled enamel the teeth are of normal form but present two different types of color change. They may have an opaque paper-white appearance but more frequently are irregularly mottled or stained yellow, brown or even black. The outer glazed enamel surface, Nasmyth's membrane, is present and appears to be normal, except in those cases which are termed 'corroded'. The brown stain can not occur unless the fundamental mottled defect of the enamel is present and may never develop. This alteration in the appearance of the enamel is highly disfiguring and once established cannot be remedied short of a difficult operative procedure. Moreover, practically every child born and reared in an area in which this condition is endemic is certain to have the condition to some degree. Thus the importance of this affliction will readily be appreciated. The Pittsburgh Section of the International Association for Dental Research has recently devoted an entire program to a discussion of the nature, geographical distribution, and cause of mottled enamel.

The occurrence of mottled enamel at and near the town of Bauxite, Arkansas, has been studied by Kempf and McKay*. This community derived its water supply from wells about 255 feet deep. This deep-well water

had a disagreeable alkaline taste, and many of the families continued the use of spring water for drinking. Evidence collected during the examination of school children showed that (1) No cases of the enamel defect antedated the introduction of the deep-well water. (2) The oldest individual having this enamel defect was born about the time that the deep-well water was introduced. (3) All individuals who had used the deep-well water during any considerable period of enamel formation exhibited the defect. (4) No individual whose enamel had developed elsewhere exhibited the defect. (5) Certain individuals who were residents of this community and attended school there, but who actually lived beyond the distribution of the deep-well water and depended upon the original shallow wells, exhibited only normal enamel. Since the enamel of the temporary teeth almost never shows the defect and the calcification of the permanent teeth does not begin, on the average, until about one year after birth, it is evident that maternal nutrition is not even remotely related to the development of mottled enamel. The food supply of this group of people is from a central store with the staple articles produced and manufactured

*KEMPf, G. W. and MCKAY, L. L. Mottled enamel in a rural population. *Ir. Dent. Soc. J.*, 1932, vol. 121-140. (Reprinted in *J. Dent. Health Report*, 1933, vol. 2, 223.)

elsewhere. Locally grown products are used to some extent, but the diet of those exhibiting the enamel defect was similar in every respect, except as to source of water, to that of those who escaped.

In the town of Benton, about five miles distant from Bauxite, 124 children were examined. Of these, 103 were native to Benton and neighboring communities exclusive of Bauxite and these all showed normal enamel. The remaining 21 had formerly lived at Bauxite for longer or shorter periods. Of 16, who had lived in Bauxite for one year or more, 11 had mottled enamel.

On the strength of the evidence brought out by this study, together with reports of similar experiences elsewhere, it was decided to abandon immediately the deep-well water supply and to use water from the Saline River which was the source of supply of Benton. Oakley, Idaho, had previously abandoned its otherwise satisfactory water supply because of its apparent causal relationship to mottled enamel.

Ordinary methods of water analysis failed to identify the causal agent. While there were marked differences between the waters, these differences were not unlike those found in many other regions in which the native population remains entirely free from this enamel defect regardless of what the source of the water used might be. However, Churchill² reported the dis-

covery of A. W. Petrey, using spectrographic methods, of fluoride in the deep-well water from Bauxite. He subsequently obtained samples of water from Colorado Springs, a well near Kidder, S.D., a well near Ledgerwood, S.D., and Oakley, Idaho,—all localities in which the enamel defect was known to exist. The presence of fluorides was shown definitely in all cases. Quantitative estimation is difficult and is believed to give low values, but by the best method available the fluoride content of these waters was found to range from two parts per million for Colorado Springs to 13.7 parts per million for the deep-well at Bauxite, Ark. The survey was then broadened to include the water supplies for a number of cities, widely scattered, in which mottled enamel does not occur. Sixteen were found to have fluorides present, but in all cases to an amount less than one part per million.

The prevalence of mottled enamel in St. David, Arizona, was brought to the attention of investigators at the University of Arizona, in 1930 by A. E. Bard, a dentist of Tucson. Upon investigation³ it was found that, with the exception of one family of three children living seven miles south of St. David and the sister-mothers of two other St. David families, every person born and reared in St. David, or coming there at an early age, showed mottling to varying degrees in every permanent tooth. Although

²CHURCHILL, H. V. The occurrence of fluoride in some waters of the United States, Jr. Dental Research, 1932, xii, 141-148. (Reprinted from Industrial and Engineering Chemistry, 1930, Anal. ed. 2, 263.)

³SMITH, M. C., LANEZ, EDITH, and SMITH, H. V. The cause of mottled enamel, Jr. Dental Research, 1932, xii, 149-159. Also Technical Bull. No. 32, Agricultural Experiment Station, University of Arizona.

mottled enamel was absent from the teeth of domestic animals in St David and had never been described from other endemic foci, the experimental production of mottled enamel in rats, guinea pigs and dogs was attempted. Diets in which calcium and phosphorus were present in deficient amounts, or in disproportion to each other, also those lacking in vitamin D, failed to produce abnormality entirely similar to the characteristic mottled enamel of man. Also, using both normal and abnormal diets, certain animals were given drinking water from St David and a control series received distilled water. No destructive effect of the St David water was noticed when the diet was adequate in all respects. When, however, the diet was deficient enough in itself to produce observable changes in the teeth, all the animals receiving the St David drinking water gave evidence of this interference at an earlier age.

Realizing that the greater rate of growth of the incisors of rats as compared to children might influence the results of the experiment, further series of animals were given St David water which had been concentrated to one-tenth of its original volume. In some instances the water residue was incorporated in the ration. Positive results were now obtained. Even though the diet was adequate in all respects, the enamel of rats receiving residue from St David water quickly lost its translucency and normal yellow pigment, becoming whiter and more opaque than that of litter-mates receiving the same basal ration but with

distilled water. In a month's time, the enamel of the affected animals was not only dull and chalky white in appearance, but also pitted and corroded. The condition produced seemed to be closely identical with the mottling of human teeth.

In another group of experiments, chemical compounds were added to the food or water, using such as for one reason or another had been suspected of interfering with enamel calcification. When sodium flouride in concentrations of 0.025, 0.05, and 0.1 per cent was added to the diet, the incisors of rats began to lose their luster within a week, and in a month a corroded, pitted condition of the enamel could be observed. In 1925, McCollum had noted the abnormal color in the teeth of rats when amounts of fluoride only slightly above those occurring in natural foods had been added to the diet. Wells in the neighborhood of St David show a fluoride content of from four to seven parts per million. The well-water used by the family having the only children without the defect, that had been born and raised in the community, had a fluoride content of less than one part per million.

This work must be considered as advancing proof that mottled enamel is due to the fluoride content of the water supply of the afflicted communities. It adds another criterion to the list of those which must be taken into account in judging the suitability of a water supply. The 'brown stain' of mottled enamel is evidently a secondary condition and as yet has not been satisfactorily explained.

Abstracts

Early Lesions of Rheumatic Endocarditis.
By TIMOTHY LEARY, M D (Arch Path., 1932, xiii, 1-22)

The position of the author as medical examiner gave him opportunity to study the early phases of rheumatic endocarditis in persons who came to violent deaths while in apparent full health, or who died suddenly without hospitalization. Three patients, in the series utilized, provided the principal material. One was an apparently healthy boy of six years, whose death was due to violence, with an endocardial lesion of the mitral valve before verruca formation. An intermediate phase was found in a girl of 18 years, who had had mitral stenosis for eight years before her death, with an endocardial lesion of the tricuspid valve associated with verrucae formations in various stages. A late phase was obtained from a man, aged 51, who had an old, but not advanced, mitral process, with the lesion on the mitral valve, and showing pseudoverrucae due to thrombus formation. In the first case the contact edge of the valve was covered by a continuous layer of cells set on edge at right angles to the valve surface, giving the effect of an orderly palisade of cells guarding the injured valve surface. This must be interpreted as a reaction of defense against an injurious agent located on the surface. The cells of the palisade are believed to be evolved from fibroblasts. In the second case, the tricuspid valve showed a similar palisade arrangement between the verrucae and in the regions where no verrucae were found. In the third case pseudoverrucae made up of blood clot were found attached to areas of the mitral valve where there was a partially necrotic, dense and relatively acellular connective tissue. From this material it was possible to trace the evolution of the verrucae. Following injury to, and necrosis of, the cell palisade, the underlying fibro-

blastic tissue proliferates and groups of fibroblasts bulge upward at right angles to the surface underneath the hyaline necrotic masses. As the resulting verruca enlarges, histocytes appear among the fibroblasts [The phases of this process are well illustrated by 23 figures]

Streptococci Agglutination in Glomerulonephritis By B J CLAWSON, and MACNIDER WETHERBY (Proc Soc Exp Biol and Med, 1932, xxix, 566-567)

The streptococcic agglutinating titers of the serums of 20 patients with glomerulonephritis were determined for a strain of streptococci recovered from the blood of a patient having acute rheumatic fever. All serums agglutinated in dilutions as high as 1 800. Five agglutinated at 1 800, ten at 1 1600, one at 1 3200, three at 1 6400 and one at 1 12800. The agglutinating titers of these serums were considerably higher than those found with the same strain with the serums of 110 normal individuals, of 50 patients with acute rheumatic fever, and of 300 patients with chronic arthritis. The relative height of the streptococcic agglutinating titers in glomerulonephritis suggested (1) an etiologic relationship and (2) a possible biologic method for differentiating renal insufficiency due to glomerulonephritis from renal insufficiency associated with primary hypertension.

Bacteriological Investigations on the Blood, Synovial Fluid and Subcutaneous Nodules in Rheumatoid (Chronic Infectious) Arthritis By MARTIN H DAWSON, M D, MIRIAM OLYSTEAD, A M, and RALPH H BOOTS, M D (Arch Int Med, 1932, xlix, 173-180)

In this study the term 'rheumatoid arthritis' is used to designate that form of chronic multiple arthritis more commonly called 'chronic infectious' or 'atrophic ar-

thritis One hundred and five blood cultures, the majority in duplicate, were carried out on 80 patients suffering from rheumatoid arthritis, according to the technic of Cecil, Nicholls and Stainsby. As control material, 31 samples of blood from normal persons and 16 samples of sterile agar were subjected to similar manipulations. The blood cultures from patients suffering with rheumatoid arthritis failed to yield organisms that would be considered of etiologic significance. No significant difference was observed between the bacteria found in the blood cultures of patients and those observed during the culture of the control material. *Streptococcus viridans* was encountered occasionally during the culture of the control material as well as during the culture of specimens of the patients' blood. Twenty-three specimens of synovial fluid from patients with rheumatoid arthritis yielded no organisms of etiologic significance. Aerobic and anaerobic cultures of 12 subcutaneous nodules obtained from patients with rheumatoid arthritis likewise failed to yield organisms that could be considered of etiologic significance.

Elliptical Human Erythrocytes By M C TERRY, M D, E W HOLLINGSWORTH, M D and VICENTE EUGENIO, B A (Arch Path., 1932, xiii, 193-206)

The authors have collected 50 instances of elliptical human erythrocytes, and have added two additional cases of their own. The autopsy findings in one case are given. Aside from a reddish purple color and semi fluid consistency in the bone marrow of the femur, no changes which could be associated with the anomaly of the erythrocytes were found. When the blood of one of the patients was subjected to the action of hypotonic salt solution, the oval cells resembled normal erythrocytes in their behavior rather than the poikilocytes of a patient with anemia. The oval shape of the cells was shown to depend upon structural and not upon local environmental factors. The oval cells were found to be heavier than the round cells, and also more resistant than the round cells to the hemolytic action of hypotonic salt solution. An analysis of the entire group of cases estab-

lishes the condition as a hereditary anomaly which is not incompatible with health, which may occur in whites, blacks and mulattoes, and which is about equally divided in incidence between the sexes. It may be transmitted through either the male or female, and a generation may be skipped. All four blood groups are represented among the reported cases.

The Syndrome of Adrenal Hemorrhage in the New-Born By MAX A GOLDBLUM, M D, and MURRAY B GORDON, M D (Endocrinology, 1932, xvi, 165-181)

Thirty-seven cases of adrenal hemorrhage in the new-born and 38 in older infants, all offering some clinical information, were gathered from the literature. To these, six personally observed instances, of which five were diagnosed during life, have been added. From a study of these 81 cases it was concluded that an *intra vitam* diagnosis of adrenal hemorrhage in the new-born may be made on the basis of a definite syndrome. This consists of two groups of symptoms: those due to acute adrenal insufficiency and those produced by internal hemorrhage. Either one of these may predominate. Acute insufficiency is made known by acute onset, high temperature, rapid respirations, petechial or purpuric rash, cyanosis and metabolic changes—especially hypoglycemia. Associated with these are gastro-intestinal and nervous disturbances. These may be accompanied or masked by signs of internal hemorrhage (shock collapse, weak pulse) and local signs of abdominal distress: distention and the presence of a mass in one or both kidney regions. Suggested therapy consists of intravenous transfusion of blood, injection of glucose and the administration of a potent adrenal cortical extract.

Iodine Poisoning and Iodism from Iodol By D A CAMMISHELL, M D (Canadian Med Assn J., 1932, xvi, 319-20)

Two cases are described in which a combination of iodism and iodine poisoning followed the use of Iodol. The first patient had received 20 cc of Iodol by the hypodermic method. Six days later he became acutely ill with symptoms of iodine poisoning, pain in the throat, sore throat, and a face, yellowed and covered with a brownish

carial wheals over the knuckles, wrists, forearms, forehead, nose, lips, chin, cheeks, ears, and sides of the neck. These became bullous vesicles, many of which were hemorrhagic. Tough crusts formed, beneath which the epithelium regenerated, and recovery without scar formation was complete at the end of three months. A second patient gave substantially the same symptoms and signs following the supraglottic introduction of 30 c.c. of lipiodol to confirm a diagnosis of bronchiectasis. The author believes that this combination of the irritant poison effects of iodine with the skin eruptions of iodism in these cases must indicate rapid absorption from the gastro-intestinal tract and that this is made possible by swallowing the sputum. He suggests that patients should be instructed that at no time during the procedure, or afterwards as long as the taste or smell of oil is recognized, should the sputum be swallowed. Careful search during the fluoroscopic examination will reveal any lipiodol in the stomach and if sufficient to contain even one grain of iodine, it should be removed either by gastric lavage, induced vomiting, or a brisk

saline cathartic. Starch may be given as an antidote and continued as long as the vomited or aspirated material has a blue color.

A Pathologic Study of the Criteria Differentiating Chronic Gastric Ulcer, Cancer-on-Ulcer and Ulcerating Carcinoma of the Stomach. By W. H. BUEERMANN, (Northwest Medicine, 1932, xxxi, 49-54.)

From various sources the criteria to be applied in recognizing the development of gastric carcinoma upon gastric ulcer are assembled. In this manner the history of the evolution of this clinico-pathological conception is traced. The author finds that, at the present time, there is fairly general agreement that carcinoma does develop secondarily in a small percentage of chronic gastric ulcers. Definite pathologic criteria must be laid down and strictly adhered to in differentiating cancer-on-ulcer from ulcerating carcinoma. Clinically, the danger lies not so much in the possibility that cancer will develop upon a given gastric ulcer, as that an early ulcerating carcinoma may be masquerading as a benign calloused ulcer.

Reviews

It is with pleasure that attention is called to the fact that all of the books selected for review this month deal with the History of Medicine. This is a good sign. It is another indication of the growing interest in the cultural side of our work. It is in line with the increasing recognition given the subject of Medical History on the program of the San Francisco Meeting of the College, with the successful continuation in this country of such a journal as the *Annals of Medical History*, and with the increasing strength of both local and national societies for the prosecution of the study of this subject.

This is a period of notable anniversaries in Medical History. Less than two years ago was celebrated the tercentenary of the introduction of cinchona into medicine of the civilized world. This year, on October 24, another tercentennial should be noted, the birth of Antony van Leeuwenhoek. On March 24, the medical world did honor to the memory of Robert Koch, for fifty years before that day he announced the discovery of the tubercle bacillus.

It is well that so many local histories of medicine are being written. There should be one for every state and province. Material should be re-

interested in the History of Medicine. Seventy-five per cent of it can be read with interest by any practitioner and all of it is of great value for purpose of reference

Imhotep to Harvey Backgrounds of Medical History By C N B CANNIC, M.D., Assistant Professor of Clinical Medicine, College of Physicians and Surgeons, Columbia University, New York Foreword by HENRY FAIRFIELD OSBORN, ScD, LL.D. xxv + 324 pages, 4 illustrations, five tables Paul B Hoeber, Inc, New York City, 1931, Price \$3.75

The author's seminars for fourth year medical students of The College of Physicians and Surgeons of New York are reflected in the pages of this book. In a series of chapters, each of which might serve as the basis for an informal exercise in Medical History, the background of the subject is developed. Preceding each the subject matter is briefly outlined, and in the last 20 pages, book lists are given, arranged to illustrate and complement the material of each chapter. Thus this book lends itself particularly to the library method of presentation. Illustrative material is found in a group of historical records and quotations from, or about, Servetus, Harvey, Copernicus, Galileo, Descartes, and Spinoza. We agree with the distinguished author of the foreword, that "The present volume will serve as an introduction to longer works, bringing the History of Medicine within the reach of medical undergraduates and those novices and imitators with whom the art of healing may become a delightful vocation if not a vocation. To this large and rapidly increasing class of professional and nonprofessional readers we heartily recommend 'Introduction to Harvey Backgrounds of Medical History'."

This edition of the History of Quebec is in the Province of Quebec and is not for the publication of the Province of Quebec. It is not a publication of the Province of Quebec. It is not a publication of the Province of Quebec. It is not a publication of the Province of Quebec.

covering the period from the discovery of Canada to 1800, the late Dr Georges Ahern assumed responsibility. The second part, 1800 to the present time, was particularly assigned to Dr Abbott. Through the death of Dr Ahern it became necessary for Dr Abbott to assume the responsibility of bringing this material together in a unified form. Dr Abbott has succeeded in presenting a very interesting and informative account of the medical history of the province. While concerned with tracing the larger movements and the growth of significant institutions, Dr Abbott has made free use of original sources with quotations, personal anecdotes, official records, and other citations which add greatly to the interest. The sections on Primitive Medicine, Scurvy among the First Settlers, the Rise of the Early French Hospitals, Michel Sarrazin, Inoculation and Vaccination, Great Epidemics of the Nineteenth Century, and Dr James Barry are all of much more than local interest. Dr Abbott has made a worthwhile contribution, not only to the Medical History of the Province of Quebec, but to that of the New World.

A Doctor of the 1870's and 80's By WILLIAM ALLEN PUSEY, sometime President of the American Medical Association and of the American Dermatological Association. xiii + 153 pages. Illustrated. Charles C Thomas, Springfield, Illinois. Price, \$3.00 postpaid.

As a boy, the reviewer read and reread a simply written book entitled "The Country Doctor". Its authorship has long ago passed from memory, but its faithful reflection of the life and activities of a general practitioner in the prairie country rang true, and the skillful blending of comedy and pathos made an indelible impression. In Pusey's book we find again the record of the life and activities of the general practitioner in a rural community. This alone would justify its writing, but here the picture is drawn with skill and with tenderness. Between the lines one senses the anxiety of the son who fears that he will write too much of the virtues of his hero-father, and at the same time fears he is writing too little to measure up to what he knows to

have been the just estimate of the man. This book should live on. It is not only a contribution to Medical History in the United States, but it is also a human document good to be read by the medical sons of medical fathers for more than one generation.

California Medicine (A Review) By JOHN WILLIAM SHUMAN, M.D., F.A.C.P. 182 pages. A. R. Elliott Publishing Company, 53 Park Place, New York City. Privately printed.

As previously stated it should be a source of great satisfaction to all interested in the history of Medicine in the United States that so many local histories have appeared in the last few years. This timely effort on the part of Dr Shuman has made possible the preservation of the evidence of eye witnesses to many highly significant developments. In but a few years more such accounts will have become impossible. In *California Medicine*, the author records much that is of value, particularly to those whose special interest is in Los Angeles and its environs. To others medical, it will prove entertaining and informative, especially in regard to Indian and early Spanish Medicine and the doctors of the Gold Rush days. The author is to be congratulated on his easy narrative style. It is to be regretted that but a very limited edition is available.

Builders of American Medicine Being a Collection of Original Papers Read before the Victor C. Vaughan Society of the University of Michigan Medical School viii + 243 pages, 9 illustrations. George Wahr, Publisher, Ann Arbor, Michigan, 1932. Price, \$2.00.

At the University of Michigan a self-perpetuating group of senior medical students is organized as The Victor C. Vaughan Society for the study of Medical History. The present volume contains twelve essays read before this group during the year 1930-31. The "Builders" who are the subjects of these essays are Zabdiel Boylston, Benjamin Rush, Ephraim McDowell, William Beaumont, Samuel D. Gross, Sr., Oliver Wendell Holmes, Austin

Flint, William Pepper, Silas Weir Mitchell, John Shaw Billings, Walter Reed and Victor C Vaughan. Naturally, a senior medical student can seldom be a researcher in Medical History in the sense of bringing forth new knowledge from hitherto unknown or unappreciated original sources. Yet the vigor and freshness of the enthusiastic amateur stand out in these chapters, which must, of necessity, be largely fusions of tales that have been told before. This attractive little book deserves a wider distribution than that which it is likely to receive.

The History of Medicine A Short Synopsis By BERNARD DAWSON, M.D. (Lond.), F.R.C.S. (Eng.) xiv + 160 pages, 31

illustrations. The Macmillan Company, New York City, 1932. Price \$2.50.

This small book contains a series of lectures delivered to junior medical students of Adelaide University. These lectures are intended to portray the continuity and increasing volume of the stream of medical knowledge rather than to present the details of the History of Medicine. The material is presented under seven chapter heads: Primitive Medicine, The Grecian Period, The Greco-Roman Period, the Dark Ages and the Hippocratic Tradition, The Middle Ages and the Universities, The Renaissance, and The Period of Consolidation. The style of this book is pleasing and the typography excellent. It can be recommended as fulfilling its stated purpose.

Dr Guy G Iunsford (Fellow), Commissioner of Health, Milton, Georgia, addressed the annual meeting of the Georgia Public Health Association, January 22, 1932, on "Typhoid and Sanitation."

Dr Arthur C Morgan (Fellow), Philadelphia, Pa., was recently appointed by Governor Pinchot of Pennsylvania as a member of the State Board of Medical Education and Licensure.

Capt Kent C Mellorn, M.C., U.S.A. (Fellow), Washington, D.C., was promoted lately from the Bureau of Medicine and Surgery, Navy Department, to the State Department, as a member of the American Delegation to the General Disarmament Conference. General Mellorn is also a member of the American Medical Association.

the Medical Corps of the Navy in 1907. Since September, 1930, Captain Melhorn has been in charge of the Division of Personnel, Bureau of Medicine and Surgery.

Dr. Hyman I Goldstein (Associate), Camden, N. J., is the author of an article in the *Medical Times* (N.Y.) for January, 1932, entitled "Mitral Stenosis." He is also the author of an article in the *Journal of the Medical Society of New Jersey* for February, 1932, entitled "Erythema Nodosum and Erythema Multiforme," and of one in *International Clinics* (Phila.) for March, 1932, entitled "Recent Advances in Treatment."

Dr. E. J. G. Beardsley (Fellow), Philadelphia, Pa., Governor for Eastern Pennsylvania, was the guest speaker at the Cambria County Medical Society at Johnstown, Pa., on February 11, 1932. His subject was "The Science and the Art of Medicine."

Dr. David E. Markson (Fellow), Chicago, Ill., read a paper entitled "Newer Concepts on Etiology and Treatment of Arthritis" before the DuPage County Medical Society on January 16, 1932. On January 28, he presented the "Report of a Case of Diabetic Coma, with Blood Sugar of 900 mg., with Recovery" before the staff of the Norwegian American Hospital, and on March 3, addressed the North Side Branch of the Chicago Medical Society on "Therapeutic Fever in the Treatment of Arthritis."

Dr. John L. Garvey (Fellow), Milwaukee, Wis., recently presented a paper on "Calcified Angiomas of the Brain," together with a report of a case, before a meeting of the Chicago Neurological Society.

At a Symposium on Arthritis given by the Section of Internal Medicine of the Los Angeles County Medical Association on February 3, 1932, the following Fellows of the College contributed to the program:

"Arthritis Due to a Definite Organism"

Dr. Roland S. Cummings, Los Angeles
Discussion opened by Dr. Roy Thomas, Los Angeles

"Arthritis Due to Metabolic Disturbances"
Dr. S. M. Alter, Los Angeles,
Discussion opened by Dr. Paul B. Roen, Hollywood

"Arthritis Deformans"

Dr. John V. Barrow, Los Angeles
Dr. John W. Shuman, Los Angeles, is President of the organization and Dr. John V. Barrow, Los Angeles, is Secretary. Dr. S. M. Alter was Chairman for the Symposium.

Dr. Edward J. Engberg (Fellow), St. Paul, Minn., read a paper on "The Present Extent and Value of Annual Registration" before the Federation of State Medical Boards of the United States held in Chicago on February 15 and 16, 1932, in connection with the Annual Congress on Medical Education, Medical Licensure, and Hospitals.

Dr. Paul J. Connor (Fellow), Denver, Colo., was elected President of Staff of the Presbyterian Hospital of Colorado at a meeting of the Staff in January.

Dr. Erwin D. Funk (Fellow), Wyomissing, Pa., is in Germany pursuing further studies in Pathology.

An interesting Annual Report of the St. Edwards Mercy Hospital of Ft. Smith, Ark., was recently received. Dr. S. J. Wolferman (Fellow) is Chief of Staff. Dr. Arless A. Blair (Fellow) is Vice President of the Clinical Staff as well as being a member of the Executive Staff.

Dr. Edward V. Goltz (Fellow), St. Paul, Minn., was elected President of the Ramsey County Medical Society at the November meeting.

Dr. Lorenz W. Frank (Fellow), Denver, Colo., was elected President of the Medical Society of the City and County of Denver at the annual meeting on January 4, 1932.

Dr. Edward W. Jackson (Fellow), formerly of Rochester, N. Y., has recently become associated with the Ponton-Brown

Clinic Hospital of Edinburg, Texas, as Chief of the Medical Staff

Dr William Engelbach (Fellow), New York City, addressed the American-Hungarian Medical Association at the New York Academy of Medicine on February 15, 1932, his subject being "The Growth Hormone" Dr Englebach also delivered an address on "The Anterior Pituitary Lobe" before the Bedford Medical Society, February 25, 1932

Upon examination of the March 1 issue of *Progress Notes* published by the Atlantic City Hospital, Atlantic City, N J, we note that the following Fellows and Associates of the College are on the General Staff for 1932 Dr Samuel Barbash (Fellow), Dr D Ward Scanlan (Fellow), Dr Samuel I. Salasin (Fellow), Dr Clarence L. Andrews (Fellow), Dr Sidney Rosenblatt (Associate), Dr Harold S. Davidson (Fellow), Dr Philip Marvel, Jr (Fellow), and Dr Hilton S. Read (Associate) Dr Philip Marvel, Sr, (Fellow) and Dr W. Blair Stewart (Fellow), Governor for New Jersey, are Honorary Members of the Staff

Dr Frederic J. Farnell (Fellow), Providence, R. I., Chairman of the Public Welfare Commission, State of Rhode Island, is the author of a signed article appearing in *The United States Daily*, Washington, D. C., February 17, 1932, entitled "Plan for Public Welfare Work in Rhode Island"

The following Fellows of the College are members of the Committee on Nominations of the National Tuberculosis Association: Dr Stuart Pritchard, Battle Creek, Mich., Chairman, Dr Frederick T. Lord, Boston, Mass., Dr Munford Smith, Los Angeles, Calif. At the Twenty-eighth Annual Meeting of the National Tuberculosis Association, to be held at the Antlers Hotel, Colorado Springs, Colorado, June 6-9, 1932, Dr Pritchard will give the Report of the Committee on Nominations.

At this meeting, according to the Preliminary Program, the following Fellows will present papers: Dr Gerild B. Welch,

Colorado Springs, Dr Clarence L. Hyde, Akron, Ohio, Dr John W. Flinn, Prescott, Ariz., Dr E. K. Geer, St. Paul, Minn., Dr H. A. Burns, Ah-gwah-ching, Minn., and Dr Carl H. Greene, Rochester, Minn.

Dr I. D. Bronfin (Fellow), Denver, Colo., will speak at the Spring Meeting of the American Sanatorium Association, June 6 and 7, 1932, to be held at the Brown Palace Hotel, Denver, Colo., and F. E. Harrington (Fellow), Minneapolis, Minn., and Dr Benjamin W. Black (Fellow), Oakland, Calif., will appear on the program of the American Public Health Association, whose Western Branch Meeting will be held June 9-11, 1932, in Denver.

Dr Ada E. Schweitzer (Fellow), Indianapolis, Indiana, Child Hygiene Director for the Indiana State Board of Health, Division of Infant and Child Hygiene, is responsible, in conjunction with Dr Wm. F. King, State Board of Health Commissioner for Indiana, for the novel idea of designating May Day as Child Health Day in that State. Pamphlets have been broadcast to homes, churches, and institutions of various kinds throughout the state, suggesting programs of activity and instruction along health lines for use in observing this special health day. Individuals and groups putting these or other plans into practice are urged to report the same to Dr Schweitzer in order that the movement may incorporate permanently the advances made this year.

Dr V. C. Rowland (Fellow), Cleveland, Ohio, was the guest of Dr A. B. Brower (Fellow), Dayton, Ohio, Governor for Ohio, at a dinner at the Van Cleve Hotel on March 4, 1932. Later the same evening he addressed the Montgomery County Medical Society on "Differential Diagnosis of Chronic Colitis." In route to Dayton, Dr Rowland had spoken before the Fayette County Medical Society at Washington, O., Ohio, in connection with the celebration of Diphtheria Immunization, subject being "Periodic Health Examinations." At this meeting he reported on the Periodic Health Examination of the Children of the State Medical Association.

Dr Alfred Friedlander (Fellow), Cincinnati, Ohio, delivered an address before the Medical Forum of Pittsburgh on the evening of February 13, embodying the results of studies on the "Reticulocyte Count in Normal and Abnormal Conditions"

Dr Albert W Ferris (Fellow), East Orange, N J, has resigned his position as Senior Physician on the Staff of the Glen Springs Health Resort, Watkins Glen, N Y, because of illness. Dr Ferris spent nearly fifteen years in this service, besides having been formerly President of the N Y State Commission in Lunacy (now the Department of Mental Hygiene), Medical Editor for many years of the *New International Encyclopedia and Year Book*, and the author of over forty articles on medical topics, in various medical publications. He has now retired from practice and is living at 111 N Walnut Street, East Orange, N J

Dr Walter M Simpson (Fellow), Dayton, Ohio, was a guest of the Medical Service of the Fifth Avenue Hospital, New York City, on February 19, 1932, presenting a paper on "Tularemia" on that evening

Dr Charles J Bloom (Fellow), New

Orleans, held a clinic on March 3 in the city of McComb, Mississippi, and the same evening gave a paper entitled "Common Respiratory Infections in Infants and Children"

Dr Joseph H Barach (Fellow), Pittsburgh, addressed The Mohoning County Medical Society at Youngstown, Ohio, on February 16, 1932. Dr Barach spoke on the topic, "The Etiology, Classification, and Treatment of High Arterial Pressure"

Dr Anthony Bassler (Fellow), New York City, lectured to the senior students of Jefferson Medical College and to the senior and junior students of Hahnemann Medical College of Philadelphia on March 23, 1932, speaking on the Physiology of the Pancreas, with special regard to his test for judging the efficiency of the external secretion of the pancreas and its clinical application

On February 24, 1932, Dr J Reid Broderick (Fellow), Savannah, Georgia, addressed the First District Meeting of the Georgia Medical Society in Statesboro, Georgia, on the subject, "Bronchial Asthma"

OBITUARIES

DOCTOR HUGH SPAULDING WILLSON

Doctor Hugh Spaulding Willson (Fellow), died from acute coronary thrombosis at his home in La Jolla, California, on the 12th of December

Dr Willson was born in 1877 at Plain View, Minnesota. He was graduated in medicine by the University of Minnesota in 1904. After practicing as assistant city physician in Minneapolis for eighteen months he went to Crystal, North Dakota, where he practiced until 1912. Following a year's service with the Mayo Clinic at Rochester, Minnesota, Doctor Willson went to Minneapolis

where he built up a gastro-intestinal clinic in which he, and the physicians he had associated with him, conducted a large and widely known practice. At the outbreak of the war, Doctor Willson went into Military service as a consulting physician. After nine months at Camp Kearney he went overseas with Base Hospital No 70. After the war Doctor Willson reopened the Clinic in Minneapolis. He remained there until 1926, when, forced by ill-health, he went to La Jolla, California, where his wife, Mary Richmond, to whom he was married in 1907, now survives him. Doctor Willson found the rest and change to

California so beneficial that he opened offices in La Jolla. The return to activities in his profession gave him much comfort and brought him high esteem among his many friends and patients who deeply regret his untimely death.

(Furnished by EGERION CRISPIN, M.D., F.A.C.P., Governor for Southern California)

DOCTOR HOWARD H. BELL

Dr. Howard H. Bell (Fellow), St. Louis, Missouri, died January 7, 1932, age forty-seven years.

Dr. Bell was born at Lewistown, Pennsylvania, attended High School there, and later entered the Philadelphia College of Pharmacy, from which he graduated as a Pharmaceutical Chemist in 1907. In 1909 he was awarded the degree of Doctor of Pharmacy from the same institution. He entered the University of Pennsylvania School of Medicine, and graduated with the degree of Doctor of Medicine in 1912. He was Instructor in Pathology and Bacteriology at the University of Alabama, 1913 to 1919, Assistant Instructor and Associate in the Department of Pathology, and later Associate Professor of Bacteriology at the Washington University School of Medicine, St. Louis, these appointments extending from 1914 to 1924. During 1924 and the first half of 1925, he was connected with the Department of Medicine of the University of Cincinnati, and in 1925 went to the St. Louis University School of Medicine as Assistant in Medicine, which appointment he held at the time of his death. He was also Tuberculosis Controller for the city of St. Louis.

Dr. Bell was the author of many publications appearing in the leading journals of the country. During the World War he served at Rouen, Dijon, Langres, and in the Balkans. In all he served twenty-eight months in foreign service successively as First Lieutenant, Captain and Major. He was cited by the Officers Municipaux de Langres and was decorated by the King of Rumania.

He was a member of the St. Louis Medical Society, an Ex-President of the Trudeau Club, a member of the Missouri State Medical Society, a Fellow of the American Medical Association, as well as being a member of many other scientific organizations. He was elected a Fellow of the American College of Physicians on April 8, 1929.

DOCTOR MALLIE ADKIN CLARK

Dr. Mallie Adkin Clark (Fellow), Macon, Georgia, died February 6, 1932.

Dr. Clark was born in Russell County, Alabama, September 1, 1860. His preliminary education was obtained under his father's direction, and in 1885, he received his A.B. degree from Mercer University, and in 1911, his I.L.D. degree from the same institution. He received his M.D. degree from Bellevue Hospital Medical College in 1890. For several years thereafter, he practiced medicine in Bluffton and Barnesville, Georgia, coming to Macon in 1897, where he remained in active practice until the time of his death. From 1898 he was on the faculty of Mercer University as teacher of Medical Jurisprudence in the Law School and Medical Medicine in the School of Pharmacy.

Dr Alfred Friedlander (Fellow), Cincinnati, Ohio, delivered an address before the Medical Forum of Pittsburgh on the evening of February 13, embodying the results of studies on the "Reticulocyte Count in Normal and Abnormal Conditions"

Dr Albert W Ferris (Fellow), East Orange, N J, has resigned his position as Senior Physician on the Staff of the Glen Springs Health Resort, Watkins Glen, N Y, because of illness. Dr Ferris spent nearly fifteen years in this service, besides having been formerly President of the N Y State Commission in Lunacy (now the Department of Mental Hygiene), Medical Editor for many years of the *New International Encyclopedia and Year Book*, and the author of over forty articles on medical topics, in various medical publications. He has now retired from practice and is living at 111 N Walnut Street, East Orange, N J

Dr Walter M Simpson (Fellow), Dayton, Ohio, was a guest of the Medical Service of the Fifth Avenue Hospital, New York City, on February 19, 1932, presenting a paper on "Tularemia" on that evening

Dr Charles J Bloom (Fellow), New

Orleans, held a clinic on March 3 in the city of McComb, Mississippi, and the same evening gave a paper entitled "Common Respiratory Infections in Infants and Children"

He was elected a Fellow of the American College of Physicians on April 8, 1929.

DOCTOR MALLIE ADKIN CLARK

Dr. Mallie Adkin Clark (Fellow), Macon, Georgia, died February 6, 1932.

Dr. Clark was born in Russell County, Alabama, September 1, 1866. His preliminary education was obtained under his father's direction, and in 1885, he received his A.B. degree from Mercer University, and in 1911, his LL.D. degree from the same institution. He received his M.D. degree from Bellevue Hospital Medical College in 1890. For several years thereafter, he practiced medicine in Bluffton and Barnesville, Georgia, going to Macon in 1897, where he remained in active practice until the time of his death. From 1898, he was on the Faculty of Mercer University as teacher of Medical Jurisprudence in the Law School, and *Materia Medica* in the School of Pharmacy. For sev-

eral years, he was a member of the Board of Trustees of this university

Dr Clark had been an active member of the local medical society in Macon for many years, and was past President of the Medical Association of Georgia, and at the time of his death was its Parliamentarian. He was a Fellow of the American Medical Association, and was elected a Fellow of the American College of Physicians on January 1, 1921

Dr. Clark was a member of the staff of the Macon Hospital for many years, and had been a member and chairman of the Governing Board of that hospital

He was pre-eminently a student,

setting aside a part of every day for real study. His knowledge of medical sciences was well nigh encyclopedic. Those who sought of him information often said he seemed not to forget anything he had read. He gave willingly of his time and talents to those who sought his assistance, his opinion was respected. With him, his profession was his life; his recreation consisted of study of science and literature. He was devoted to his patients and felt keenly their sorrows and rejoiced in their joys

(Furnished by JAMES A FOUNTAIN, M D, F A C P, President, Medical Society of Bibb County)

The Importance of Finger-Borne Infection

IN THE transfer of this type of infection [diphtheria] from one person to another, the fingers are probably the chief agents. It has been said, 'Who can doubt that if the salivary glands secreted indigo, the fingers would continuously be stained a deep blue, and who can doubt that if the nasal and mouth secretions contain the germs of disease these germs will be almost as constantly found upon the fingers? All successful commerce is reciprocal and in this universal trade of human saliva the fingers not only bring foreign secretions to the mouth of their owner, but there, exchanging them for his own, distribute the latter to everything that the hand touches. This happens not once, but scores and hundreds of times during the day's round of the individual. Everyone is busily engaged in this distribution of saliva, so that the end of each day finds this secretion freely distributed on the doors, window sills, furniture, and playthings in the home, the straps of trolley cars, the rails and counters and desks of shops and public buildings, and, indeed, upon everything that the hands of man touch. What avails it if the germs do die quickly? A fresh supply is furnished each day.'

"Bearing in mind the aforementioned fundamental principles, the following

measures are recommended for the prevention of diphtheria, in the application of which every parent, schoolteacher, and family physician should render active cooperation (1) Strict adherence to the rules of personal hygiene, and (2) the immunization of all people who are likely to have diphtheria as shown by the Schick test"

(From *Health News*, United States Public Health Service, March 16, 1932)

Rheumatic Heart Disease

A REVIEW*

By CLOUGH TURRILL BURNETT, M D , F A C P , *Denver, Colorado*

THE large volume of literature which has appeared in recent years relating to various phases of rheumatic fever and rheumatic heart disease seemed to require some correlation. An attempt at this resulted in the following review.

While the earliest description of rheumatic fever appeared prior to the middle of the seventeenth century, and the best of these in 1676 by Sydenham, it was not until more than a century later, in 1788, that a clear description of rheumatic heart disease was published by David Pitcairn of St Bartholomew's in London. Prior to this, Storck and others had noted changes in the thoracic viscera in cases of rheumatism coming to autopsy.

Dillon,⁶² in 1850, and Gramshaw,⁶³ in 1853, used the term 'Rheumatic Carditis' in the titles of published articles. Stokes,¹ in 1853, frequently used this term. He observed that "disturbance of the heart's action, even though without any physical sign of inflammation, when arising in the course of rheumatic fever, is to be considered as showing the proclivity to, if not the existence of, carditis" (page 523), and that "rheumatic fever does not necessarily coexist with arthritis" (page

46). He also made the valuable observation—ofttimes forgotten in these later days—that the cardiac involvement may precede that of the joints (page 47).

INCIDENCE

A recent editorial appearing in *Colorado Medicine* raises the question of the value of conclusions drawn from mortality statistics in heart disease. While the inaccuracy of individual death certificates is evident, this basis of study remains at the present day the principal source of information as to the incidence and hence of the importance of any group of diseases. Therefore at the outset, reference must be made to mortality and, so far as obtainable, to morbidity statistics. During the past fifty years the deaths from tuberculosis declined 44 per cent, while the deaths from heart disease increased 42 per cent, and during the past twenty-five years in the United States Registration Area the deaths from heart disease outnumber those from tuberculosis. At the present time heart disease ranks as the leading cause of death. The local importance of heart disease is stressed by Washburn⁴ who wrote, "In Denver, deaths from tuberculosis fell from nearly 700 in 1917 to 459 in 1927 while heart deaths increased from 157

*From the University of Colorado School of Medicine

in 1917 to 449 in 1927." The same author stated, "If we attempt to classify the deaths at all ages according to etiology we can estimate that approximately 30 to 35 per cent of the whole number are due to rheumatic heart disease."

Heart disease may be divided into three age groups and these in general represent etiological groups. Up to the age of forty the great majority of cases of heart disease are rheumatic in origin. Twenty-five per cent of all cardiac deaths fall in this period.³ Of five hundred children observed by Wilson⁴ and her associates in a heart clinic, 12 per cent died and 88 per cent of the deaths were due to rheumatic heart disease. In New York City⁵ heart disease was found to be the leading cause of death among school girls. Among school boys it ranks second only to accidental death. The same records show that heart disease stands second as cause of death in young adults ranging in age from fifteen to nineteen years.

The second age period in heart disease is from forty to sixty years, when syphilis is the most important cause of death. The third period extends from sixty years on, when cardiac deaths are chiefly due to degenerative changes.

It is unfortunate that we have no satisfactory morbidity statistics, since heart disease and rheumatic fever are not reportable diseases, but Emerson⁶ estimated that for every death from heart disease there are probably seventeen people suffering from heart disease, while there are only seven cases of tuberculosis for every death. Dublin⁷ was more conservative, estimating ten cases for every death from heart

disease, and stating that at ten years of age an individual is three times as likely to die from heart disease as from tuberculosis.

Deductions drawn from the incidence of rheumatic fever are of doubtful value since the conception of what constitutes rheumatic fever is and has been rapidly changing in the past decade. Practically all figures obtainable relate to frank cases of rheumatic polyarthritis and disregard those cases presenting the nonarthritic manifestations of this disease.

During the war about 5 per cent of the men in the draft were excluded because of organic heart disease. Combined school, industrial and insurance statistics show that from 2 to 2.5 per cent of the population have some form of organic heart disease. Emerson⁷ stated that not less than 1 per cent of the population requires care for some class of heart disease. It is thus evident that as an economic load heart disease at least equals in importance that of tuberculosis.

Autopsy Statistics Cabot⁸ presents statistics from 4,000 autopsies (a total of 4143 cardiovascular lesions in 1906 persons) which show that rheumatic valvular heart disease is twice as common as syphilitic aortitis and five times as common as syphilitic valvular disease. Mitral stenosis, alone or combined, is three times as common as all other rheumatic valve lesions combined. Mitral stenosis uncomplicated is two times as common as any other single valve lesion. Figures show a falling off in the amount of fatal rheumatic heart disease but show no falling off in the amount of pericarditis. The age at the time of death is most often thirty to thirty-nine years.

The incidence of family infection in rheumatic fever is about that of tuberculosis. St Lawrence⁷ showed that in 50 per cent of families two or more persons had rheumatic infection. Faulkner and White⁹ gave 35.5 per cent as a comparable figure. Swift⁸ stressed the house and person to person infection. While there is usually a low grade of contagiousness this disease may assume epidemic proportions^{11,12}. It appears probable that the lungs serve either as a portal of entry for rheumatic infection or as a source of reactivation. Numerous authors have called attention to the relationship at times observed between bronchopneumonia and rheumatic carditis.

ASSOCIATED CONDITIONS

Coburn¹⁸ in an excellent monograph considers the relationship existing between rheumatic fever and upper respiratory tract infections, both in the initial and recurring attacks. Having noted that rheumatic fever is extremely uncommon in the tropics, he transported ten patients with active rheumatic fever from New York to Porto Rico for a period of six months, so far as possible avoiding any change in the management of these patients other than that of climate. In brief, his results showed that the rheumatic process, severe in New York, subsided during three months in the Tropics, disappeared clinically during six months in the Tropics, and evidenced itself with sudden reappearance of symptoms in some instances shortly after the return of these patients to New York. These observations strongly suggest that the rheumatic state was influenced by the change in environment.

Nichol,¹⁴ in a study of the incidence in Florida of two common diseases encountered in the colder states of this country, namely, rheumatic fever and pneumonia, notes an extremely low incidence of rheumatic fever, whereas that of pneumonia is relatively much higher. "Among 31,000 hospital records there were 10 cases of rheumatic fever or chorea and 152 cases of lobar pneumonia." He believes that we should find among children born and reared in this area practically no heart disease of rheumatic origin.

The weight of evidence seems to indicate that rheumatic fever is most frequently encountered in the temperate countries, but Paul¹⁵ furnishes some interesting exceptions to this rule. For details as to the theories and known facts relating to the geographical distribution and of family and environmental influences associated with rheumatic fever the reader is referred to his recent report.

Rheumatic fever is especially invasive in early to middle childhood and at this age period when its onset is especially insidious, the visceral phenomena (carditis, etc.) are more frequently observed than at a later period when arthritic phenomena predominate. Puberty appears to be a critical period, but following this the tendency to rheumatic infection diminishes. Girls appear to be definitely more susceptible to rheumatic carditis. In addition to rheumatic fever, chorea, tonsillitis and other types of streptococcal infection of the respiratory tract, scarlet fever and puerperal sepsis have been considered to bear an etiological relationship. Swift¹⁶ especially stresses the importance of streptococcal focal infections (tonsillitis,

sore throat, pyorrhea and apical abscesses) as predisposing factors in rheumatic fever and rheumatic heart disease. It must be admitted, however, that in the majority of cases of focal infection this relationship is assumed rather than proved

Newsholme, in England, showed the greatest number of cases to occur in those years in which the annual rainfall is lowest, while in the United States the disease is most prevalent in the spring months. Against the theory of dampness being a factor is the fact that during the war in France rheumatic fever was noted to be comparatively rare in spite of the exposure in trench life.

Because of the intimate relationship which exists between rheumatic fever and chorea, it is generally assumed, though by no means proven, that the infectious agent is identical. Riesman and Small¹⁷ include chorea as a manifestation of rheumatic fever. The incidence of the appearance of rheumatism antecedent to chorea varies according to different authors from 9 to 71.5 per cent. In Oxford Medicine¹⁸ appear the following figures on the incidence of rheumatism antecedent to chorea.

Apt and Levinson	143 cases	9 per cent
Branson	67 cases	71.5 per cent
Collective Investigation		
Committee of B. M. A.	439 cases	26 per cent
Osler	554 cases	15.8 per cent
		had acute or subacute joint swelling either preceding or subsequent to chorea

While these figures appear contradictory, it must be borne in mind that there is often great difficulty in determining the presence of fleeting articular involvement, that vague joint and muscle pains are not always sus-

ceptible of exact classification and that the rheumatic infection may not become manifest until after the chorea has passed away. Nodules occurring in the vicinity of joints in chorea are, according to Kaufmann,¹⁹ analogous to Aschoff bodies and hence furnish further evidence of the etiological unity of these two diseases.

It seems desirable to stress this relationship of chorea and rheumatic heart disease since not all pediatricians appear to recognize it. Waggoner²⁰ in a recent article on chorea barely mentions this relationship and in his consideration of treatment makes no mention of the prevention of heart disease in chorea or of the care of the choreic cardiac patient. In the present state of our knowledge it is wise to search diligently for a history of frank or masked chorea in childhood in connection with the obtaining of the history of any cardiac patient.

BACTERIOLOGY

No attempt will be made to review all of the literature relating to this phase of the subject. There appears, however, to be a unanimity of opinion that some form of streptococcus, or perhaps many forms are capable of

producing rheumatic fever and its sequel, rheumatic heart disease. The work of Small^{21,22} and his associates has attracted considerable attention in recent years, although this work has not been substantiated by other work-

ers He presented the *Streptococcus cardioarthritides*, which possesses a specific immunity identity Isolated first from the blood of the rheumatic fever patient, then from the throat, it is claimed that it is capable of producing characteristic arthritic and cardiac pathology in rabbits, including Aschoff nodules, and that a specific serum can be prepared with it

The organism is a spherical Gram-positive coccus which in fluid medium yields diffuse growth and shows short chain formations It is readily stained by the ordinary aniline dyes It is nonmotile, aerobic and facultatively anaerobic Neither flagella, spores, nor capsules are demonstrable It is of rather constant, uniform size, varying from 0.7μ to 1.2μ in diameter The optimum temperature for growth is 37°C , but growth at low temperatures occurs Regarding sources of *Streptococcus cardioarthritides*, Small in his recent report mentioned only the throat and blood and evidently doubted his former finding from feces He stated that the organism is found regularly in throat culture in cases of rheumatic fever or chorea and has been obtained in three instances from blood in rheumatic fever Cultures should not be made from the crypts of intact tonsils, since these usually show *Streptococcus viridans*, *hemolyticus*, etc, but from the superficial sites in the pharynx—pillars, uvula and soft palate

That other organisms than *Streptococcus cardioarthritides* may be the cause of rheumatic fever and the usual manifestations of rheumatic heart disease was shown by Tredway,²³ who reported the case of a boy of $13\frac{1}{2}$ years who had had two previous attacks of

rheumatic fever with carditis In the third attack there was a mild pharyngeal infection with a septic temperature running to 103° The blood culture showed *Streptococcus viridans* on three occasions Later there was pericarditis and effusion Rheumatic nodules were noted at the end of the twelfth week and were present only on the scalp There were no petechiae or other evidences of emboli The only joint involvement was in the left metacarpals and left shoulder for but four days The reasons given for reporting were the unusual blood findings, the absence of joint symptoms, except as above, and pericarditis with effusion Small²⁴ pointed out that from the clinical standpoint confusion has arisen in the differentiation of rheumatic endocarditis and bacterial endocarditis, particularly in the transition stages of the former into the latter A streptococcus obtained in the blood culture of a patient might arise from either the one or the other of these conditions

Clawson²⁵ tabulated the bacteriological results of blood, joint and pericardial exudate cultures as reported by various workers and states, "The conclusion to be drawn from the findings of the various workers on the basis of morphologic, cultural and immunological characteristics is that the group of streptococci isolated from cases of rheumatic fever cannot be considered a specific one, but that it represents a heterogeneous group, generally green-producers on blood agar, with moderately low virulence"

Cecil,²⁶ et al, found a streptococcus—usually *viridans* in type—in the blood and joints of a high percentage of rheumatic fever patients They

noted, however, that indifferent or even hemolytic streptococci may occur.

In addition to our lack of accurate knowledge as to the causative organism, we are likewise uncertain as to whether there is direct bacterial invasion in all cases, or whether there is simply a local tissue reaction, allergic in nature, to toxins produced at some distant bacterial focus. Comparative studies of rheumatic fever, tuberculosis and syphilis suggest that in the former, as well as in tuberculosis and syphilis, there is an allergic factor. Swift²⁷ demonstrated that the intradermal injection of living streptococci into rabbits produced not only an immediate inflammatory reaction, but in addition a later but milder inflammatory reaction, which occurred in the absence of living streptococci in the involved tissues. He also showed hypersensitivity of the skin of rheumatic fever patients to streptococci, which he interpreted as a specific allergic manifestation. Kinsella²⁸ has cited another example of allergy which apparently occurs in gonorrheal rheumatism. He pointed out that gonorrheal arthritis never occurs in the early state of the urethritis but after several weeks or months and then apparently associated with some other condition which permits a blood invasion. Then we have a totally different response on the part of the body to bacterial invasion.

PATHOLOGY

Limitation of space prevents any extensive consideration of pathological changes, but it should be stressed that rheumatic carditis is usually a pancarditis, that while the acute involvement of the pericardium and myocar-

dium is usually transient and clears with little or no permanent impairment of these tissues, that of the endocardium usually leads to deformity with resultant hindrance to the filling and emptying of the heart chambers—a condition which secondarily leads to muscle damage.

Lasèque²⁹ wrote, "Rheumatism licks the joints, the pleura and meninges but bites the heart."

No attempt will be made to present a systematic description of the pathological changes in rheumatic heart disease, but in the course of this review certain investigations and ideas presented by the various authors were sufficiently striking to merit comment. Reid³⁰ classified pathological lesions in rheumatic fever as exudative and proliferative, the former changes are found in the joint and serous cavity involvement, the latter in the endocardial and myocardial changes and in the subcutaneous nodules which so frequently accompany this disease.

The two working theories as to the cause of valvulitis are: (1) That trauma of contact of the valve cusps at the line of closure resulted in the lodgment of organisms at this point with subsequent formation of vegetations, (2) That bacteria in the blood stream lodge as emboli in normal capillaries which occur in the valve leaflets. Kerr³¹ on an experimental basis concludes that both of these factors are operative in the production of valvulitis.

Opposed to the usual opinion Crummer³² stated that mitral insufficiency (organic) is one of the least frequent valve defects. But Kaufmann¹⁹ wrote, "Mitral lesions, chiefly insufficiency, constitute two-thirds of all valvular

lesions.' These figures are drawn from autopsy findings. Another interesting note regarding rheumatic valvulitis is that of Cabot,³³ who stated that he had never seen a proven case of tricuspid valvulitis, although Libman³⁴ and Thayer³⁵ have shown its occurrence in 44 and 66 per cent of their cases respectively.

The infrequency of early right sided lesions may be due to the fact that in early life the blood supply to the right heart is comparatively better than to the left.

The most commonly mentioned myocardial lesion is that described by Aschoff—the Aschoff nodule, a sub-miliary collection of large spindle-shaped or branching cells containing large, at times multiple, nuclei. These giant cells, usually grouped in a radiating or fan-like arrangement and occurring in the interstitial tissues, are sub-endocardial and usually perivascular. While this is mainly a proliferative reaction, there may be associated a varying number of polymorphonuclear leucocytes, lymphocytes, eosinophiles and plasma cells. The centers of these nodules undergo necrosis and may later become completely fibrosed. When these occur in the interventricular septum there may be serious involvement of the conduction system with varying degrees of block resulting. Aschoff and others considered these to be pathognomonic of rheumatic myocarditis, but in the past decade groups of giant cells, which could not be readily differentiated from the Aschoff body, have been occasionally demonstrated in other conditions, in general in infections due to streptococci of low virulence. It is thus apparent that while in rheumatic carditis

there is a tissue reaction which is usually characteristic of the disease, the finding of these bodies—in the absence of other evidence—must not be accepted as proof of the existence of rheumatic myocarditis.

Von Glahn³⁶ feels that changes in the left auricular endocardium, previously described by McCallum, are as distinctive and characteristic as the Aschoff bodies. These changes consist of irregular furrows and ridges on the endocardium which terminate at the line of closure of the mitral valve leaflet. In these are found polymorphonuclear leucocytes, small and large mononuclears and wandering cells—a cell group with none of the characteristics of the Aschoff bodies.

As an explanation of the absence of mitral stenosis in advancing rheumatic carditis Smith and Sutton³ stated, "Fibrosis of the mitral valve does not always cause narrowing of the channel because the walls of the ventricle become weakened by the lesions in the musculature, so that the ventricle and the auriculoventricular rings become stretched. In spite of the cicatrization, the mitral channel is thus often held open, making the opening larger than normal and allowing regurgitation." Later in discussing mitral insufficiency they state that the early mitral insufficiency is due less to the condition of the valves than to the myocardial factor which causes muscular relaxation, permitting stretching of the rings.

The earlier descriptions stressed the importance of valvular lesions and of the Aschoff nodule as an evidence of the myocardial lesion, but other studies, notably those of Klotz,³⁷ have shown that certain portions of the

arterial system are as frequently attacked in rheumatism as is the musculature of the heart Klotz, Allbutt,³⁸ Von Glahn⁴⁰ and others stressed the importance of aortitis, aneurism, pulmonary artery lesions similar to those in the aorta, and peripheral vascular lesions in rheumatic fever. Discussing aortitis, syphilitic and rheumatic, Klotz noted, "In syphilis the disease rarely comes to a standstill, at least in so far as the recognized and studied cases indicate." In rheumatic disease of the aorta the process usually comes to an end spontaneously, but always predisposes the involved areas to recurrent attacks. Regarding the frequency of aortitis in rheumatic fever he stated, "The almost constant presence of some inflammatory reaction in the ascending limb of the aorta should be recognized as an associated condition in this disease."

Allbutt³⁸ stated that rheumatic aortitis is not rare but usually unrecognized; being usually superficial, it is often painless and in most cases it arouses no symptoms. Numerous other authors have cited cases of aortitis and aneurism in children, of rheumatic origin and often associated with typical anginal symptoms.

Myocarditis may occur in the absence of demonstrable valvulitis. Cabot³⁹ reported the case of a boy of fifteen who had a fibrous rheumatic myocarditis, particularly of the left auricular wall. There was no acute endocarditis but fibrous thickening of the mitral and tricuspid valves without stenosis or noteworthy insufficiency. Dr. T. B. Mallory stated that this was the second case seen in four months—a pure rheumatic myocarditis.

Mackenzie,⁴⁰ in discussing peri-

carditis, stated that when pain is present it will be found invariably that there is evidence of myocardial affection. Swift⁸ stressed the fact that pericarditis is not of itself painful. Regarding the frequency of myocardial involvement there are varying opinions. Aschoff bodies, the accepted pathological evidence of myocardial involvement, are demonstrated frequently at autopsy, but whether they frequently or always occur with the first attack is a question which has caused considerable controversy. Allbutt²¹ wrote that the myocardium is probably involved in every case—the endocardium and then pericardium coming next in order. The first symptom is usually palpitation and stabbing pain over the heart or a feeling of tightness or oppression in the left breast.

Coronary changes have not been considered of importance in rheumatic heart disease until very recently. Perry,⁴¹ in 1930, reported eight autopsies upon cases of rheumatic fever carditis showing coronary changes. This study was incited by the findings at the autopsy of a child who during life suffered from typical anginal pain in the course of a severe rheumatic carditis. The main branches of the coronary arteries showed severe intimal thickening, with a considerable reduction in size.

Any discussion of coronary and myocardial changes in rheumatic fever and rheumatic heart disease would be incomplete without a reference to the electrocardiographic evidence of these changes. Peel,⁴² Wyckoff,⁴³ et al., have noted changes in the T wave and in the conduction time. Wyckoff and his associates noted wide and inconstant variations in the A-V conduction

time and that there is no proof that they are influenced by salicylate therapy

Master⁴¹ reported the frequent finding of flat T waves in one or more leads and noted that in subsequent observations these waves may become inverted, or if taken at a later period may again become upright, indicating in either case a progressive myocardial change. Slater,⁴⁵ in a recent report, presented three cases which showed inversion of the T waves occurring in the course of rheumatic fever. These were all in adults, suggesting a greater arterial vulnerability. This author believed that this represents a coronary occlusion, not necessarily due to thrombosis, "but that the specific lesion in the vessel may be the site of considerable edema, as in any exudative condition, and that this may account for the closure."

Certain authors⁴³ have attempted to formulate diagnostic criteria based upon the type and degree of T wave changes. A review of the material in the Colorado General Hospital and of cases seen in private practice fails to substantiate these claims. For the present it would seem preferable to depend upon evidence of arrhythmias, of conduction disturbances between the auricles and ventricles or within the ventricles, and abnormal preponderance of one side of the heart. Not infrequently the electrocardiogram will furnish the only sign of cardiac involvement—in fact, cases have been reported in which these changes have occurred before any other evidence of rheumatic infection had become manifest.

Pericarditis Cabot⁶ stated that the pericardium in childhood is more

sensitive than in later life, hence pericarditis is more frequently encountered at this period. Allbutt,⁴⁶ writing in Oxford Medicine, stated that the incidence of pericarditis in rheumatic fever is about 10 per cent. He had the impression that pericarditis is less frequent in rheumatic fever than a generation ago and suggested that salicylates may have more of a protective influence in pericarditis than in endocarditis. Pericarditis may precede any grade of arthritis in the young, in older cases it is found only in the severer forms. Combs⁸ stated that 53 per cent of all cases of all ages show pericardial changes at autopsy—though not clinically. Rheumatic pericarditis is never suppurative. Regarding pericardial effusions, Mackenzie⁴⁰ has never found any serious embarrassment of the heart from even extensive effusions.

The question as to the frequency of carditis in rheumatic fever has attracted considerable attention. Swift⁸ stated, "The infection in childhood leads more frequently to cardiac sequelae, indeed it is often questionable whether the first tissue to be attacked by the virus in the early years of life is not that of the heart." In a series of eighty-one rheumatic fever patients⁴⁷ he obtained electrocardiographic evidence of functional cardiac disturbance in over 90 per cent. Wilson,⁴ et al., stated, "The heart is probably always effected at the onset of this [rheumatic fever] disease." White¹⁰ stated, "The rheumatic infection usually or always involves the heart."

All recognize the tendency of mitral stenosis to remain "silent" throughout many years after the acute rheumatic attack. Yet there must in many cases

be some progress during this interval Riesman and Small¹⁷ conclude that the cardiac involvement is part and parcel of the rheumatic process and is no more a complication or a sequela than is involvement of the shoulder joint a day or two after that of the knee joint. Certain other authors state that they have never seen a child below ten years of age suffer from rheumatic fever without involvement of the heart. Mackie⁴⁸ analyzing 366 cases of rheumatic fever found that at five years of age 61.5 per cent, and at ten years 78 per cent, presented evidence of carditis in the first attack. Washburn² in a recent paper read before the Denver County Medical Society stated that he was certain carditis did not always occur, that he had followed a considerable number of children in which there was never any evidence of carditis. Certainly the failure to demonstrate carditis during an attack is insufficient proof of an intact heart since the murmurs of endocarditis may only be demonstrated months after an attack.

Von Glahn³⁶ presented some interesting figures relative to the possible duration of active rheumatic carditis. In his series of 109 cases he noted that 35 of the cases had a free interval from arthritis of one to thirty-eight years, yet had acute rheumatic disease at the time of death, and that in 50 per cent of those with arthritis, acute rheumatic cardiac lesions may be found when there has been freedom from joint attacks for intervals as long as thirty-eight years. In other words, there is either reinfection without joint symptoms, or persistence of the infection in masked or latent form—often over many years.

With each decade of life there is

less liability of permanent cardiac damage in rheumatic fever, which means that for the prevention of rheumatic heart disease the early attacks of rheumatic fever must be prevented. Typical acute rheumatic fever is rare after forty, for at this period of life polyarthritis is apt to be preceded by a "cold" or influenza, and the cardiac picture is quite different from that associated with childhood rheumatism.

As a means of prevention of rheumatic fever in childhood, tonsillectomies have been extensively performed on the theory that the tonsils represent the primary site. Certain it is that the incidence of rheumatic fever is greatest in the young where there is an excess of lymphoid tissue. Swift's series shows that tonsillitis is an antecedent of rheumatic fever in about 50 per cent of cases. Kaiser,⁴⁹ in a study of 439 rheumatic fever children, found that nearly twice as many children developed the first attack of rheumatism when the tonsils had not been removed and that after tonsillectomy recurrent attacks occurred 10 per cent less frequently, but in general the results of tonsillectomy have been disappointing in the prevention of rheumatic carditis. A tonsil stump may retain sufficient infection to cause a recurrence or an initial rheumatic infection. Riesman and Small¹⁷ obtained cultures of *Streptococcus cardioarthritides* from the "superficial sites in the pharynx" and suggested that surgical removal of the tonsils will not eradicate these foci. Katz⁵⁰ described these foci as "post-operative foci." It is probable that the tonsils are only one of the portals of entry and that any infection of the up-

per respiratory tract may prove equally responsible

At the present time we have no certain method for the prevention of rheumatic infection in childhood, but much can be accomplished toward the prevention of cardiac sequelae if the earliest manifestations of rheumatic carditis are recognized. Childhood rheumatic carditis may occur in a mild form with symptoms only of undue fatigue, pallor, loss of weight and appetite, or failure to grow and gain in weight, and only slight dyspnea on exertion. On examination, aside from moderate anemia and undernutrition, with slight increase in pulse rate, there may be no demonstrable signs. These cases present a striking similarity to tuberculosis. In connection with the milder symptoms the frequency of effort syndrome at puberty should be recalled.

When rheumatic fever is denied, search for a history of chorea, frequent tonsillitis, fleeting growing pains and purpura. The frequency and severity of infantile and adolescent pneumonia, pleurisy and painful conditions of the chest may be evidence of earliest heart disease.

CLINICAL PICTURE

In any discussion of the clinical picture of rheumatic heart disease it is necessary to stress first some of the variations in the clinical picture of acute rheumatic fever. The classical picture of acute rheumatism is too well known to require repetition but some of its variants may deserve mention. The migratory arthritis may be absent. Von Glahn³⁶ in a series of 109 cases found 41 "who never had arthritis." There may be only pain and tenderness without swelling. In chil-

dren the disease tends towards chronicity while in adults the attack is characterized by its explosiveness. According to Swift,⁸ "In the adult the arthritis and visceral complications, if they occur, are usually seen within a short period of a few weeks—in children, on the other hand, although the disease is ushered in by an acute onset, the various groups of symptoms may make their appearance months apart." In the latter, nervous symptoms, chiefly the manifestations of chorea, are likely to occur. These may consist simply of nervousness, irritability and clumsiness, or the jerking movements typical of the disease. Frequently observation over a considerable period is necessary in order to establish a diagnosis.

The importance of pulmonary and pleural involvement in rheumatic carditis should be stressed. A left sided fibrinous pleurisy (near the heart) occurs in from 5 to 10 per cent of cases. Pneumonia may mask the picture of rheumatic fever, a condition I described in 1928 under the title of Occult Rheumatism.⁵¹ There has been some discussion as to the occurrence of a specific rheumatic pneumonia. Aschoff bodies have been described³ in the pulmonary arteries and other characteristic changes in the arterioles of the lung. These pulmonary changes occur more frequently in cases of pancarditis, although they are described as occurring sometimes independent of arthritis or carditis, as in a case reported by myself.⁵¹ It is well to consider this possibility with the occurrence of a "wet pleurisy", for this may be due to rheumatic fever as well as tuberculosis. Paul⁵² has recently published a comprehensive review of

the literature on pleural and pulmonary lesions in rheumatic fever

Subcutaneous nodules occur chiefly in children, rarely in adults. Three types are described: (1) Miliary, in tendons and sheaths; (2) Medium-sized, in broad tendons that pass over joints and at insertions; and (3) Large, over bony surfaces beneath the skin. Nodules usually occur in severe forms of rheumatic infection and have been thought to suggest a poor prognosis, but recently White¹⁰ suggests that they may indicate a favorable reaction. These nodules may be noted late and may not occur on extremities, as in the case of Tredway²³ previously cited, in which they appeared at the end of the twelfth week and were present on the scalp only.

The rash in rheumatic fever (*Erythema multiforme*) may come in crops with each new involvement of the joints. This occurs at some period in about 15 per cent of the cases, but this sign, as well as the nodule, is less frequently observed in this country than in England. Less frequent skin manifestations are *erythema nodosum*, *urticaria*, *purpura* and *petechial hemorrhages*. These are the most frequent symptoms of heart invasion—only rarely are pain and dyspnea complained of during the acute stage. Later, if symptoms occur, they are those of congestive failure.

Disturbances of Rhythm Swift⁸ states that 20 to 30 per cent have transient conduction disturbances. Auricular and ventricular premature contractions are frequent. Auricular fibrillation and flutter, also heart block, are serious complications. Mackenzie¹⁰ cites as a rarity a case of auricular fibrillation in a child of five

years suffering from rheumatic fever. Associated with these, Neuhof⁶¹ describes "thumpings" occurring with a normal rate, thought by him to be due to "abnormally strong ventricular contractions", and describes also sensations of weight and pressure on the chest not unlike the anginoid pains described by Allbutt. These precordial sensations, except as found in the psychoneurotic type of patient, surely indicate myocarditis or the aortic involvement described by Allbutt.

Pulse The pulse without heart complications is proportional to the temperature. A high pulse after the disappearance of arthritis is strong evidence of carditis. A slight acceleration of the pulse may precede by several days the physical signs of endocarditis.

Murmurs Prior to the appearance of a murmur the heart sounds may be muffled due to edema of the valves or may be increased due to ventricular hypertrophy. A systolic murmur without persistent cardiac enlargement and regardless of transmissions is insufficient evidence of organic mitral insufficiency—for even functional murmurs may be heard in the back.

Conclusive signs of stenosis only appear after fibrosis and contraction, which is months after the initial infection. Mitral stenosis, rheumatic in origin, may show only a systolic murmur while the heart is beating slowly. If the rate be increased by exercise or by some drug (amyl nitrite) a diastolic murmur may be heard, likewise a mid-diastolic murmur may be heard only in the recumbent posture. In the absence of a murmur in

diastole, early, mid-, or late, or a definite presystolic murmur, the need of special investigation should always be suggested by a history of chorea or rheumatic fever when there is an unusually sharp first sound, a systolic murmur which begins abruptly, an increased or doubled pulmonary second sound—especially when the second sound at the apex is diminished in intensity—and by the presence of auricular fibrillation or a break in compensation not due to some other cause. Any loud apical systolic murmur in childhood warrants a careful search for signs of mitral stenosis.

Pericarditis This is not of itself painful, with the onset of temperature and pulse increase one should look for a rub, but because of the evanescent character of pericardial rubs the failure to demonstrate one does not preclude pericarditis.

Cardiac hypertrophy, disproportionate, or not explained by other lesions, suggests adhesive pericarditis. An absence of shifting with postural changes noted in the fluoroscope and electrocardiogram are further evidences of adherent pericardium, but some of the other signs usually associated with adherent pericardium may have a different cause. Systolic retraction at the apex and sternum may be due to right ventricular hypertrophy. Pulsus paradoxicus (waxing and waning with respiration) is present in myocardial insufficiency and in many normals. Diastolic collapse of cervical veins (Friedrich) is not characteristic, since it is seen also in auricular fibrillation. Broadbent's sign may be due to an enlarged heart pulling on its attachments to the diaphragm.

Fever A temperature of 102° to 104°, if this increase occurs without new joint involvement, suggests visceral involvement. Light fever for weeks or months after the acute symptoms is strong evidence of cardiac involvement, especially when accompanied by leucocytosis*. The lesion may be in the myocardium or mural endocardium.

Sudden pallor, restlessness and nausea, pulse increase with albuminuria and liver enlargement in the course of, or subsequent to, rheumatic fever strongly suggest shock due to splanchnic dilatation.

PROGNOSIS

This depends upon the age at which the initial infection occurs and the frequency of recurrence of rheumatic infection. With a slight lesion, protection throughout life, and luck, the individual may carry a rheumatic valve lesion with very little if any disability and reach the normal life expectancy, but more frequently cardiac sequelae cripple the patient for years before he finally succumbs**. Cohn⁵⁸ stated that an average period of fifteen years

*Recent studies indicate that the sedimentation rate may serve as a useful indication of existing cardiac infection.

**In a recent article Morse⁶⁴ analyzes 100 consecutive cases of acute rheumatic (?) endocarditis, seen in the first attack and followed over a period of 10½ to 26½ years, and comments on the relatively small number of deaths (36), the small number of cardiac invalids (3), and the large number of complete recoveries (61). Of this group of 61 cases who had completely recovered, Morse found 37 in whom the hearts appeared normal on examination. Even allowing for a certain small factor of diagnostic error, this percentage of apparently normal hearts is so striking as to merit comparable studies by other competent observers.

elapses between the initial attack of acute rheumatic fever and the death of the patient from the resulting heart disease Christian⁷⁴ places a comparable figure at twenty years and White¹⁰ at ten to twenty years. In adult life there is much less likelihood of additional rheumatic valve involvement due to recurrent rheumatic infection, but far greater danger of auricular fibrillation, with the frequently resulting congestive heart failure, and of a *Streptococcus viridans* infection as an added insult to the existing rheumatic endocarditis. Patients with aortic valve lesions or mitral lesions which are predominantly regurgitant are somewhat more prone to viridans infection than are those with mitral stenotic lesions. Most important is the certainty of progression in the mitral stenotic lesions. Allbutt states that pericarditis in an adult always carries with it a poor prognosis.

COMPLICATIONS

Congestive heart failure, auricular fibrillation and subacute bacterial endocarditis (*Streptococcus viridans*) constitute the most important complications. Congestive heart failure occurs in at least two-thirds, fibrillation in one-fifth and viridans infection in 4 per cent of all cases of rheumatic carditis according to figures furnished by White¹⁰.

TREATMENT

Salicylates Regarding the treatment of rheumatic fever Swift⁸ advised us to obtain the maximum effect of salicylates to the point of beginning toxicity, rest one day and then give a smaller dose. Crummer³² felt that cases properly treated show less tendency to pericarditis and "endo-

cardial changes" and tend to earlier stabilization. Leech⁵¹ believed there is a definite advantage in giving daily rations of salicylates to children who represent actual or potential instances of rheumatic heart disease. There is no evidence of any effect of the drug on the slowly progressive development of mitral stenosis.

While Mackenzie¹⁰ taught that there is a specific action of the salicylates on the rheumatic heart, the general opinion appears to be that this drug is less efficient in its action on the heart than on the joint tissues. This difference in response on the part of different tissues has some experimental basis. Hagebush and Kinsella⁵⁰ showed that the allergic dermal reactions produced in rabbits in the course of chronic focal streptococcal infection could be entirely prevented by salicylates, while the vascular lesions remained unaltered. Small⁵⁷ stated that there is a difference in response to salicylates in the proliferative (heart) and exudative (joint) lesions. Wyckoff⁴³ showed that salicylates have no effect on the A-V conduction time. It would seem that the prophylactic use of salicylates during any acute respiratory infection might be of value in reducing the number of cases of rheumatic fever and hence of rheumatic carditis. Quite recently it has been shown⁵⁸ that by the simultaneous administration of magnesium sulphate or chloride (grams 2 to 4) and salicylates there is a distinct augmentation of the effect of the latter. This process is described as potentiation and is comparable to that observed when magnesium salts are administered with morphine.

Digitalis Schwartz⁵⁹ stated that in

childhood nausea and vomiting occur as a late manifestation of digitalis action, whereas slowing of the sinus rate occurs early but is a transitory phenomenon, never lasting more than four to seven days. If digitalis is pushed further, block occurs. He believed that nausea and vomiting cannot be safely used as criteria of digitalization in rheumatic valvular heart disease with failure. Schwartz also said that digitalis in adequate doses can produce both the transient and permanent forms of auricular fibrillation in children with heart disease. This may be an early manifestation of its toxic effect and may result fatally. He concluded that digitalis is contraindicated in children with rheumatic fever and signs of cardiac insufficiency. Allbutt³⁸ advised against digitalis in the acute stage.

Levy and Golden⁶⁰ suggested roentgen therapy in rheumatic carditis. They believed this modifies the lesions, basing their opinion upon alterations in the form of the electrocardiogram, and felt that in thirty cases of rheumatic heart disease the clinical course was apparently influenced in twenty-one. In their article I find no mention of similar electrocardiographic observations in a control series—as in a series of noncardiac cases—a point of considerable importance since roentgen exposure is known to cause changes in the heart muscle.

Clawson²⁵ showed that "lesions similar to those found in rheumatic fever can be produced in animals" by the injection of streptococci and that animals so sensitized can be protected from these rheumatoid lesions by intravenous streptococcus vaccination.

He concludes that since rheumatic fever patients are hypersensitive to streptococci, intravenous vaccination with streptococci "may be indicated in acute rheumatic fever."

Swift,¹⁸ et al., in a recent article presented a very complete review of vaccination with streptococci in rheumatic fever. They advanced a working hypothesis which assumes hypersensitivity to streptococci associated with continuous or repeated low-grade focal infection. If at any time an acute infection supervenes—as tonsillitis, or sinusitis—this hypersensitivity increases. They stated, "These irritants appear to attack those mesenchymal tissues most subject to physiological trauma, hence lesions commonly occur in such constantly moving structures as joints, tendons, heart and blood vessels." They further stated, "In patients with active disease, both febrile and focal reactions following vaccination have many resemblances to true rheumatic relapses and that these can either be prevented or terminated by anti-rheumatic drugs, is highly suggestive", and that "the sensitization responsible in part for the pathogenesis of rheumatic fever was induced by strains closely related to hemolytic streptococci."

Discussing the advantages of intravenous over subcutaneous vaccination they show that in animals the "injection of streptococcal vaccines into the tissues usually tends to sensitize, while intravenous injections tend to diminish the overactivity of hypersensitive tissues, and therefore the logical method would be intravenous inoculation under proper precautions." In addition the local reactions about the

site of subcutaneous vaccination with streptococci are often so intense that patients are unwilling to have them repeated. Intravenous injections, on the other hand, are free from local reactions, and most patients are willing to continue them for a full course, hence, from both a theoretical and practical point of view, the intravenous route is the one of choice. This form of treatment Swift considered especially applicable to two classes of patients: (1) Those with a continuing low-grade infection, and (2) those temporarily free from symptoms, but in whom relapses may reasonably be expected. They seem to show a distinct result from the intravenous administration of a vaccine made from hemolytic streptococci. "In about four-fifths of the patients increasing tolerance to the vaccine was accompanied by improvement."

Discussing treatment by means of vaccines, anti-sera and soluble products of bacteria, Small⁵⁷ stated that there are three main methods of attack upon the tissues in rheumatic fever: (1) Local growth of streptococci, (2) General toxic effect of streptococci, (3) Other bacterial products distributed from a focal source and capable of inducing and maintaining the allergic state. Probably these seldom act singly. Small's working hypothesis assumed that the visceral (vascular and cardiac) lesions on the one hand and the joint lesions on the other are caused by a different mechanism. The former are due to a specific endotoxin, the latter to the establishment of hypersensitiveness to a protein fraction contained in numerous streptococci, an example of the production of a specific allergin of di-

verse biologic origin. "The problem in therapy of acute rheumatic fever appears to be that of complete neutralization of the toxic factor by a specific antiserum without passively transferring to the patient hypersensitization to the protein antigen common to different streptococci." The focal reaction in joints following the administration of Small's antiserum is a manifestation of this passive transfer of allergy, therefore the protein fraction must be removed. To accomplish this he uses his "soluble antigen."

In the treatment of rheumatic fever and its visceral complications Small²² reported results in 1928 as follows:

There were prompt beneficial effects in 251 patients with chorea and acute rheumatic fever. In these were acute arthritis, endocarditis, myocarditis, pericarditis, pleuritis, pneumonitis and subacute nodules. In chorea the twitchings subside promptly and usually disappear in one week. This serum should be used as early as possible and is not contra-indicated by carditis. If the patient is sensitive to horse serum Small furnishes a bovine antiserum following the administration of which severe urticaria, febrile reactions and arthralgia are less common. Further, to prevent severe reactions, the serum is given in divided doses to patients acutely ill.

Vaccines proved to produce reactions in deep seated rheumatic infections, so were discontinued in favor of soluble antigen, but this was not used except as a followup treatment after the antiserum, and as a prophylactic it is again given in the spring and fall for several years, giving six to twelve injections with each series. Small

especially emphasizes the importance of avoiding noteworthy reactions

From the foregoing it will be evident that, although a great deal of work has been done along the line of biological treatment of rheumatic fever in its various manifestations, there is no uniformly accepted biological treatment

Rest The chief method of therapeutic attack in rheumatic carditis has been left to mention last. Complete bed rest at the earliest appearance of any manifestation of rheumatic fever and until all evidence of any type of acute rheumatic involvement is past will offer the greatest assurance of prevention of extension of the process to the heart, if this be possible, and if not will furnish the greatest surety of a limitation of that process and a minimum of cardiac damage

Rheumatic carditis ordinarily dates from childhood rheumatism. Every rheumatic child, if not actually, is po-

tentially a cardiac patient. Even in the absence of demonstrable carditis the child with rheumatic fever or chorea should be treated as a cardiac patient, which means primarily rest over a long period. With such a treatment the physician will cure many early cases of cardiac rheumatism and, if not so fortunate, will at least prevent many of the sequelae which determine whether the child should enjoy comparative health or invalidism

Prevention of rheumatic carditis The foregoing paragraph probably embraces all that we know definitely regarding the subject. Rheumatic fever appears to be a communicable disease with about the same tendency to family infection as has tuberculosis. Presumably the prevention of upper respiratory tract infection will in the future materially reduce the incidence of rheumatic fever and rheumatic heart disease

Early Manifestations of Rheumatic Infections in Young Children*

By C C McLEAN, M D , F A C P , *Birmingham, Alabama*

THE early manifestations of rheumatic infections in children are characterized by an insidious onset. Such children are pale, easily fatigued, have poor appetites and are not gaining in weight as they should. Many complain of slight pains in the legs, feet or joints. There is often stiffness of limbs or neck. Digestive disturbances with paroxysmal abdominal pains are common. There is a change in disposition. The children become irritable, nervous, peevish and are easily frightened. Often there is a failure in mental concentration and they begin to drop objects and at times have difficulty in writing. There may be slight muscle twitching. Examination shows an anemic child who is irritable, nervous, excitable, high strung and usually underweight.

The second heart sound is accentuated, with a soft blowing systolic murmur heard over the apex, that may or may not be transmitted. When the murmur is heard in a patient in whom it did not previously exist and is known to remain constant for at least

a month, during which time the patient is free of temperature and acute infections, the diagnosis of a rheumatic infection is almost certain. Often no murmur is heard, but the heart action is rapid and the apex impulse exaggerated.

In the registration area¹ the death rate from organic heart disease has been increasing gradually for a long series of years. In 1910 in New York City,² the death rate due to heart disease was 175 per 100,000 population. In 1925 the rate was 266 per 100,000 population, showing an increase of 34 per cent. Drolet tells us that heart disease in New York is now responsible for more than one-fifth of the total deaths.

Wyckoff and Lingg³ analyzed 1000 cases of heart disease and found 25 per cent to be rheumatic, 40 per cent arteriosclerotic, 10 per cent syphilitic and 10 per cent of unknown etiology.

Munly⁴ analyzed 1300 cases of heart disease and found that the rheumatic type comprised 35 per cent of the total, arteriosclerotic, 33 per cent, syphilitic, 8.5 per cent, unknown, 20 per cent. Of the unknown group it is believed by most investigators, that they are chiefly of rheumatic origin, the

*Read before the Chattahoochee Valley Medical and Surgical Association, Radium Springs, Ga., July 14, 1931. Received for publication, October 22, 1931.

heart condition being the only manifestation of the rheumatic infection

In the registration area in the United States in 1928 in children between the ages of 5 and 15 years, rheumatic infections and their complications caused as many deaths as any disease, with the exception of the various types of pneumonia.⁵ The American Heart Association stated, "if present conditions continue, one in every five of population living at age 10 will die of heart disease"

Feer⁶ stated that 80 or 90 per cent of all cases of rheumatic infection will have a certain degree of heart involvement. Riesman and Small⁷ stated that cardiac involvement is part and parcel of the rheumatic process and is no more a complication or sequella than is the involvement of the shoulder joint a day or more after that of the knee. Coombs⁸ states, "The heart may be damaged without manifestations of the infection. Every child that has rheumatic polyarthritis, which can be recognized as such, may be assumed to have an affected heart." Still⁹ in his excellent book wrote, "There is no more pitiful sight than seeing a child dying from rheumatic carditis. It is hoped that by recognition of these cases in the early stage, that some of the terrible results can be prevented."

It has been found that heart disease reduces the span of life by practically one-half. It is a well known fact that an established heart lesion in the early stages can often become stationary by the cooperation of the patient who receives the proper medical supervision and instruction. Rheumatic infections are thought to be responsible for approximately 10 per cent of

the total cardiac deaths, the majority of the patients contracting the heart condition in early childhood.

From the above observations and statistics it seems logical that the way to reduce the mortality from rheumatic heart disease is to prevent its development in every way possible. If every child with early manifestations of rheumatic infection was considered a potential cardiac patient and managed accordingly, and the parents and patient educated to the danger of the condition, the mortality from rheumatic disease would be reduced in both childhood and adult life.

The following is a report of clinical observations in 258 patients, observed in private practice, with early manifestations of rheumatic infections. Of this number 132 were boys and 126 girls. One hundred eighteen of the patients were reported in 1929.¹⁰ The largest number of cases were seen in the late winter and early spring. Fifty-eight per cent of the patients were seen in the months of January, February, March, and April. The largest number of cases were seen in March.

The following are the ages when the children were first seen with manifestations of the infection: 75 between 2 and 5 years, 86 between 5 and 7, and 97 after the age of 7 years.

Every patient had all or some of the following symptoms. They were pale, high strung, nervous, irritable children, easily fatigued, with poor appetites, who were either losing weight or not gaining as they should. Two hundred three, or 80 per cent, gave histories of repeated attacks of tonsillitis. Two hundred two, or 78 per cent, had soft blowing systolic heart murmurs. No child is included in this

series as having a heart murmur except those patients in whom the murmur was known to exist and remain constant for at least one month, during which time the child was free of temperature and acute infections.

One hundred seventy-five, or 68 per cent, gave histories of pains in the extremities or stiffness of the joints. One hundred fifty-four, or 60 per cent, were 7 per cent or more underweight for height. Seventy-one, or 28 per cent, gave histories of digestive disturbances characterized by paroxysmal abdominal pains. In 70, or 27 per cent, there were signs and symptoms of a mild chorea. Of this number 38 were girls and 32 boys. Many gave histories of night terrors, enuresis and tachycardia.

TABLE 1
The Number of Children and the Percentage Underweight for Age and Height

Percentage Underweight	For Age No. Patients	For Height No. Patients
1-6	63	60
7-10	36	50
11-14	33	50
15-20	25	39
21-25	7	15
Over 25	4	0
Total	168	214

FOCI OF INFECTION

In young children apparently the foci of infection were largely in the tonsils, nasopharynx and teeth. Foci of infection were thought to be located as follows:

- 126 cases, tonsils and adenoids,
- 49 cases, teeth or both teeth and tonsils,
- 21 cases, chronic nasopharyngitis or paranasal sinusitis,
- 62 cases, undetermined

One hundred twenty-six, or 50 per cent, of the total number of children were known to have manifestations

of rheumatic infections before the tonsils and adenoids were removed. Of this number 114, or 90 per cent, developed systolic heart murmurs. There were signs and symptoms of a mild chorea in 11 per cent. In 29 cases in which the teeth alone were thought to be the foci of infection, heart murmurs were present in 38 per cent and signs of chorea in 62 per cent. In 20 cases in which both the teeth and tonsils were apparently the foci of infection, heart murmurs were present in 75 per cent, signs of chorea in 55 per cent. Twenty-one cases in which the nasopharynx and paranasal sinuses were thought to be the foci of infection, were either irregular patients or cases having the tonsils and adenoids removed before being seen. In the majority there were histories of repeated attacks of tonsillitis.

Of the 62 cases in which the foci of infection were undetermined, heart murmurs were present in 79 per cent, signs of chorea in 30 per cent. In the majority of these cases the tonsils and adenoids were removed before the patient was seen. In many, before the operation, there was a definite history of rheumatic infections. Approximately 75 per cent gave histories of repeated attacks of tonsillitis. Otitis media was a very common occurrence. Many of the children had signs and symptoms suggestive of a paranasal sinusitis.

Ninety-one patients, 52 boys and 39 girls, developed heart murmurs while under observation. In 54, or 59 per cent, of the cases the murmur was first heard between the ages of 3 and 6 years. A diagnosis of chronically diseased tonsils and adenoids was

made in 93 per cent of the cases. Eighty-five per cent were seen one or more times with attacks of acute follicular tonsillitis. From 1 to 2 years before the murmur was heard, 39 per cent of the children were 7 per cent or more underweight for height. At the time of murmur the number had increased to 49 per cent. In 69, or 76 per cent, of the children the murmur was heard before the tonsils and adenoids were removed. No murmur was heard in 22, or 24 per cent, of the cases until after the operation. In 6 of these 22 patients, a diagnosis of a rheumatic infection had been made before the removal of the tonsils and adenoids. Eight cases were seen at irregular intervals and it is possible that the children had the heart murmur before the operation. At the time of murmur, 30 patients gave histories of pains in the extremities. Six were treated for pains in legs before murmur was heard. Ten cases, at the time of the murmur with negative histories, developed symptoms later.

Thirty-three, or 36 per cent, of the children had digestive disturbances characterized by paroxysmal abdomi-

nal pains, the majority were of such severity that the patients were brought to the office for treatment.

CHOREA

At the time murmur was heard, 3 of the children had signs and symptoms of a mild chorea. From 1 to 4 years after the diagnosis of a rheumatic infection, 6 patients developed symptoms of a mild chorea. In 4 of the 6 cases the teeth were apparently the new foci of infection.

Twenty-four children developed signs and symptoms of a more or less chronic paranasal sinusitis after the removal of the tonsils and adenoids. In these cases there was little improvement in either their physical condition or the rheumatic infection.

LABORATORY FINDINGS

At the time the children were first seen with manifestations of rheumatic infections, white blood counts were made in 167 patients. The lowest count was 4,000, highest, 31,000, average, 11,101. Fifty-eight per cent of the counts were between 9,000 and 12,000. Differential blood counts made in 175 patients showed the

neutrophile percentage above average for the age in 61 per cent of the cases. In 33, or 30 per cent, the neutrophiles were from 15 to 35 per cent above the normal average for patients of the same age.¹¹

Hemoglobin estimations were made in 177 patients (Dare and Talquist). The lowest reading was 40 per cent, the highest, 90 per cent, average, 66.7 per cent. One hundred fifteen, or 65 per cent, of the readings were between 40 and 70 per cent. One hundred sixty-seven, or 94 per cent, were between 50 and 80 per cent.

TABLE 3

Hemoglobin Percent	No. Cases
40-50	5
50-60	31
60-70	57
70-80	53
80-90	31
Total	177

Red blood counts were made in 42 patients. There were 18, or 43 per cent, of the blood counts between 3 and 4 million, 52 per cent between 4 and 5 million, and 5 per cent over 5 million.

Our records show urinalysis in 222 of the patients. In 23 cases albumin was present, casts were found in 4, only 3 of the children proved to have a nephritis. One child was found to have a pyelitis.

Wassermann tests made in 139 children were negative.

Tuberculin tests, intracutaneous and Craig's modification of the Von Pirquet tuberculin test, were done in 198 of the patients. Fifteen, or 7 per cent, gave a positive reaction.

COMMENT

The medical profession considers tuberculosis as either active or inactive and the patient is treated accordingly. The same should be true of rheumatic infections.

Rheumatic fever and other manifestations of the infections are characterized by repeated recurrent attacks. We have often seen cases free of symptoms for months, but when the resistance of the child was lowered from any of the following causes, (1) overwork, (2) fatigue, (3) too much excitement, (4) acute infections, (5) development of new foci of infection, or (6) re-infection of old foci, new manifestations of the rheumatic infection developed.

Many of the patients seen with rheumatic carditis in both young and late adult life, had evidently contracted the disease in early childhood before their tonsils and adenoids were removed. In cases seen with manifestations of rheumatic infection before the tonsils and adenoids were removed, a large percentage developed systolic heart murmurs and a small percentage had signs and symptoms of chorea. In the cases in which the teeth were apparently the foci of infection, the nervous symptoms were more pronounced, usually the heart action was rapid and the apex impulse exaggerated. There were fewer systolic heart murmurs and a decided increase in the number of children with signs and symptoms of mild chorea.

In 9 children heart murmurs were apparently the only manifestations of the rheumatic infection. Six cases between the ages of 2 and 4 years had been seen repeatedly with attacks of acute follicular tonsillitis. Loud, blow-

Shaded column—number of patients
Black column—number of patients with heart murmurs
White column—number of patients with signs and symptoms of chorea

ing systolic heart murmurs were discovered in each case between attacks of tonsillitis. The tonsils and adenoids were removed and the murmurs have remained constant for a period of from 2 to 5 years.

Three children who did not look acutely ill or toxic, ran high and widely fluctuating temperatures for several weeks, with negative physical and laboratory findings. Later, in each case, loud blowing systolic heart murmurs developed.

In the cases reported, apparently there was little or no hypertrophy of the heart. In x-ray study, the teleroentgenogram measurements in the majority of cases taken were within the normal limits. In fluoroscopic examinations, in a few cases there was a definite prominence in the region of left auricle making the left border of the heart almost a straight line.

During the period of observation, in the majority of the instances in which the cooperation of the parents and children was obtained, the heart murmurs have remained constant, with little or no change. In a certain number of cases the heart condition has progressively grown worse. In a small percentage of cases the murmurs have apparently disappeared.

Many children made little or no improvement after the tonsils and adenoids were removed. This was especially true in cases known to have had chronically diseased tonsils and adenoids. The children who did not respond to the operation, almost invariably developed signs and symptoms suggestive of a paranasal sinusitis. The most characteristic symptoms in the order named, follow (1) The tongue is coated and breath often

bad, (2) the uvula is enlarged, swollen and edematous, stretching into a narrow thread like projection clinging to the back of the throat, (3) when the patient is made to gag and contract the muscles of the nasopharynx, a muco-purulent discharge is seen, (4) intermittent cough, paroxysmal in type of several weeks or months duration, the cough being worse at night, (5) the retropharyngeal glands, especially behind the posterior tonsillar pillar are usually enlarged.

Due to the severity of paroxysmal abdominal pains caused by a demonstrable spasmodic contraction of the intestines in 24 children between the ages of 3 and 7 years, a diagnosis of enterospasm was made. The patients were given atropine. Sixteen of the cases at the time of diagnosis had symptoms or signs of a rheumatic infection. Three of the patients later developed manifestations of the infection. The records show a diagnosis of chronically diseased tonsils and adenoids in 16 of the 24 cases.

So many of the patients were seen with otitis media and asthmatic bronchitis that the records were investigated to see if children with manifestations of rheumatic infections had been more susceptible to respiratory infections than children with no manifestations. The number of respiratory infections seen in 84 patients over an exact period of 5 years from the date of birth, is tabulated in Table 4. The infections are listed as mild and severe. The mild infections include ambulatory cases with little or no temperature, comprised principally of mild upper respiratory types of infections. The severe infections include bed cases, acutely ill with high tempera-

ture, comprised principally of so-called influenza with its various complications, acute bronchitis, acute follicular tonsillitis, etc

from 11 to 12 hours sleep They are dressed warmly and not allowed out of the house on cold, damp days They do much better in warm, dry climates

TABLE 4
The Number of Respiratory Infections Seen in 84 Patients for an Exact Period of Five Years from the Date of Birth

	No of Pts	No of Resp Inf			Aver No Resp Inf per Pt		
		Mild	Severe	Total	Mild	Severe	Total
Pts with mans of Rheumatic inf	23	81	139	220	3 52	6 04	9 56
Pts without mans of rheumatic inf	61	232	376	608	3 8	6 16	9 96

Twenty-three of the 84 patients had manifestations of a rheumatic infection, 61 patients had no manifestations of a rheumatic infection The average number of respiratory infections per patient for an exact period of 5 years from the date of birth in the rheumatic cases, was 9 56; non-rheumatic cases, 9 96 The rheumatic cases had 3 52 mild and 6 03 severe infections The non-rheumatic cases had 3 8 mild and 6 16 severe infections

MANAGEMENT

Every effort is made to keep the child's attention from the heart The patients are never told they have a cardiac condition In the management of children it is essential to obtain the confidence and cooperation of the parents by educating them to the danger of the condition

Every child with manifestations of an early rheumatic infection is given the benefit of the doubt and treated accordingly What is thought to be the focus of infection is found and removed when practical Satisfactory results are often obtained by local treatment of the focus Rest in bed and forced feeding are very important The children should have

than in cold, wet ones The danger of acute infections should be explained to the parents and the children protected in every way possible

Our routine when the patient is first seen with early manifestations of rheumatic infections, is to keep the case in bed with the exception of four hours each day, for a period of two to six weeks During the four hours a day out of bed, the child is usually allowed to do as he pleases, no restrictions being made if possible They are given a well balanced, six meal diet, with especial emphasis on liver, spinach, prunes, whole wheat breads, and cereals They are also given malt, iron, and cod liver oil

One hundred forty-four patients given rest treatment and forced feeding for 518 weeks gained 486 pounds The average number of weeks of forced feeding and rest treatment per patient was 3 5 weeks The average number of pounds gained per patient was 3 4 pounds There was an average gain per patient of 15 ounces per week

The strain of the long hours of school routine is too great for the average child with a well developed

TABLE 5

rheumatic infection. It was found necessary to remove many children from school two or three times each year and give rest treatment and forced feeding. The physical condition of certain children was such that they could attend school but half a day.

SUMMARY

1 Organic heart disease causes more deaths in the United States than any other condition. Of the total cardiac deaths, approximately 40 per cent are thought to be of rheumatic origin. In a majority of cases the disease is contracted early in childhood.

2 Of 258 patients with early manifestations of rheumatic infections, 126 were girls and 132 boys. One-third of the total number of cases were first seen with manifestations of the infection between the ages of 5 and 7 years.

3 Of the children, 203, or 80 per cent, gave histories of repeated attacks of tonsillitis.

4 Two hundred two, or 78 per cent, had soft blowing systolic heart murmurs.

5 One hundred seventy-five, or 68 per cent, had pains in the legs, joints, or stiffness of the limbs.

6 Seventy-one, or 28 per cent,

gave histories of digestive disturbances, characterized by paroxysmal abdominal pains.

7 In 70, or 27 per cent, there were signs and symptoms of a mild chorea. Of this number 38 were girls and 32 boys.

8 Two hundred forty, or 82 per cent, were underweight for their height. For the age, 168, or 63 per cent, were underweight.

9 Ninety-one patients, 52 boys and 39 girls, developed heart murmurs while under observation. In 58 per cent of the children the murmurs were first heard between the ages of 3 and 6 years.

10 In 126 patients, 50 per cent of the total number, the tonsils and adenoids were thought to be the foci of infection, 114, or 90 per cent, developed heart murmurs, 14, or 11 per cent, had signs of chorea.

11 Of 49 cases in which the teeth were apparently the only foci, or one of the foci of infection, 26, or 53 per cent, had heart murmurs, 29, or 59 per cent, had signs of chorea.

12 In 177 patients the average hemoglobin reading was 67 per cent.

13 The incidence and severity of respiratory infections, during the first five years of life, were apparently no

greater in the rheumatic than in the non-rheumatic children

14 The patients in whom the results from tonsillectomy and adenoidectomy were disappointing, almost invariably developed signs and symptoms suggestive of a paranasal sinusitis. This was especially true in the cases known to have had chronically diseased tonsils and adenoids

15 During the period of observation in the majority of instances in which the cooperation of the parents and children were obtained, the heart murmurs have remained constant with

little or no change. In a certain number of cases the heart condition has progressively grown worse. In a small per cent of cases the murmur has apparently disappeared

16 One hundred forty-four patients given rest treatment and forced feeding for a period of 518 weeks, gained 486 pounds, an average gain per patient of 15 ounces a week

CONCLUSIONS

Every child with early manifestations of rheumatic infections is a potential cardiac patient and should be managed accordingly

Causes, Classification and Differential Diagnosis of Anemias*†

Based on the Detailed Examination of Over Two Hundred Patients and
a Study of the Literature

By EDWIN F OSGOOD, M D, F A C P, and HOWARD D HASKINS, M D,
Portland, Oregon

THIS is a presentation of the views formulated during a seven years' study of the clinical and laboratory phases of anemias and the literature pertaining thereto. Details of the subjects chosen, technic used, and results of the color, volume and saturation index studies are given elsewhere.¹

It has long been customary to divide anemias into two groups. Under the term primary anemia were included cases of pernicious anemia and, sometimes, chlorosis, and under the name secondary anemia, all others. These names were given as the cause was supposed to be unknown in primary anemias and known in secondary anemias. Since this classification is illogical in that it groups unrelated conditions together and tends to discourage thinking, it should be discarded.

*From the Departments of Medicine and Biochemistry, University of Oregon Medical School, Portland, Oregon

†Received for publication, July 30, 1931

Acknowledgment is due to P. Blakiston's Son & Co., Inc., 1012 Walnut St., Philadelphia, for permission to include in this article excerpts from the Textbook of Laboratory Diagnosis by Edwin E. Osgood and Howard D. Haskins.

FUNDAMENTAL CAUSES OF ANEMIA

Obviously there are only three fundamental causes of anemia.

1 Deficient production of red cells, or of hemoglobin, or of both, either due to lack of materials (chlorotic type) or to lack of active blood-forming tissue (aplastic or myelophthisic type).

2 Abnormally rapid destruction of red cells or hemoglobin, or both, in the body (the hemolytic type, internal hemorrhage, etc., are included in this group).

3 Hemorrhage or loss of red cells and hemoglobin from the body (anemia of blood loss).

As all clinical anemias result from various combinations of these factors, they deserve special study.

1 *Deficient production of red cells*
This is the group about which we know least.

(a) Deficient supply of erythrocyte-building material. Iron, certain other metals, and probably other, as yet unidentified, substances are necessary for the formation of hemoglobin.² Hence, it is probable that deficiency in these substances leads to a low color index and more severe deficiency leads to a low saturation index. Deficiency

in stroma-building materials, the nature and occurrence of which is not known, might lead to a low volume index, or the low volume index might be secondary to a decreased supply of hemoglobin, but this is as yet pure hypothesis. The most effective therapy would be to supply the deficient substances. Chlorosis is the type anemia of this group.

(b) Aplasia of erythropoietic tissue. Here we expect absence of evidences of red cell regeneration. Therefore, reticulocytes, polychromatophilic cells, and nucleated red cells should be absent from the blood stream, and, as the other myelogenous elements are seldom³ spared*, one would expect, also, leucopenia, affecting chiefly the myeloid cells (granulocytes), and thrombopenia with the associated prolonged bleeding time, delayed clot retraction and hemorrhagic tendency. Certain poisons, especially benzol,⁴ are known to produce this syndrome, and it is probable that also some bacterial toxins can produce it. It may be pro-

*The extremely rare condition of progressive postinfectious erythrophthisis in which only erythropoiesis is disturbed is the third member of the group of specific bone marrow dysfunctions, agranulocytosis and thrombopenic purpura (some types) are the other two. In aplastic anemia, all three functions are impaired.

It seems probable that these four conditions may be merely different responses of different individuals to different quantities of the same toxin. For example, it is possible experimentally to produce pictures closely simulating any one of these syndromes by varying the doses and the duration of exposure to benzol. A further point suggesting that this is true, is that cases occur showing clinical features intermediate between any two of these conditions.

duced by excessive exposure of blood forming tissue to roentgen rays or radioactive substances⁵ and in some cases is due to almost complete destruction of marrow by invasion of other tissue (osteosclerotic anemia and rare instances of malignancy). A few cases occur for which the cause has not been determined and they are grouped under the term idiopathic aplastic anemia. The only therapy that can be expected to be effective in the aplastic cases is removal of the cause and restoration of bone marrow function, although blood transfusion may be of temporary benefit. It is theoretically possible that this deficient function might be due to absence of a normal stimulus.

The only compensatory mechanism available to the body to combat decreased formation of red cells and hemoglobin is to prolong the life of those formed (decreased rate of destruction). The evidences of this are decrease in the icterus index below 25, decrease in urobilinogen in the stools, and a greater tendency for it to be absent from the urine. It is possible, but by no means certain, that poikilocytosis and microcytosis are evidences of abnormal length of life in erythrocytes. As the same changes in the aplastic type affect the granulocytes, it is to be expected that they also will show evidence of decreased rate of destruction (increased proportion of segmented forms with five or more nuclear subdivisions).

(c) Destruction of bone marrow (myelophthisic anemia). This is usually due to invasion by other tissue (leukemias, myeloma, malignancies involving the marrow, osteosclerosis, etc.) but may be due to extensive

osteomyelitis. Although there is often an absolute deficiency in marrow, there is a tendency for that near the lesion to be irritated to abnormal activity (evidenced by unusually immature red and white cells in the blood stream) and for uninvolved marrow to be capable of compensatory hyperactivity. Attempts at compensation by decreased blood destruction may also occur. Hence, the characteristic findings are those of the causative disease (leukemia, etc.) plus the presence of immature erythrocytes (reticulocytes, polychromatophilia, nucleated red cells including megaloblasts) and old red cells (poikilocytes, great anisocytosis), immature granulocytes (even back to the myeloblast with a tendency for eosinophils and basophils to increase as well as neutrophils), and old leukocytes (cells with five or more segments), thus giving rise to a very bizarre blood picture. The color, volume, and saturation indices are variable but most often within normal limits. A low icterus index and decreased urobilinogen excretion is present when decreased red cell destruction occurs. Removal of the cause is the only therapy likely to be of benefit.

2 Increased Rate of Red Cell Destruction within the Body This may be due to extravasation of blood (hemorrhage into body cavities or tissues, hemorrhagic infarcts, etc.), to hemolysis (hemolytic poisons, some bacterial toxins, or hypotonicity of the medium, as after distilled water injections, etc.), to destruction of red cells in the blood stream (malaria), to hyperactivity of the normal blood cell destroying mechanisms, to the production by the bone marrow of red cells with decreased resistance to the factors

normally tending to destroy them, or to some abnormality in another organ (spleen?) affecting the red cells in such a way as to decrease their resistance.

The evidences of increased rate of red cells destruction will be common to all. These are an increase in the blood bilirubin (increased icterus index with negative direct van den Bergh reaction and no tendency to bilirubinuria), increase in urobilinogen in the stools and a tendency for it to appear in the urine in abnormal amounts.

If no other factor than increased blood destruction plays a part, there will be evidence of rapid regeneration of cells, because the remnants of the destroyed corpuscles and hemoglobin within the body insure the continuous presence of an excess of erythrocyte and hemoglobin-forming materials*. Hence, one would expect to find in a purely internal blood destruction anemia, an increase in young erythrocytes, other evidences of increased bone marrow activity (neutrophilia with increased proportion of immature forms, and thrombocytosis), and red cells of normal size and hemoglobin content (normal color, volume and saturation indices).

Rapid regeneration of cells by the bone marrow is the compensatory mechanism in this group, and in uncomplicated cases, removal of the cause is the only therapeutic measure indicated, for the body already contains an excess supply of erythrocyte-forming materials, from the destroyed cells.

*It is theoretically possible that interference with the transport mechanism would prevent these from being available at the point where they are needed.

It is further obvious that if regeneration keeps pace with cell destruction, a cause for anemia of this type can exist without the production of an actual anemia, but the evidences of rapid erythrocyte destruction and of rapid erythrocyte regeneration will, nevertheless, be present

3 *Blood Loss from the Body* This includes all types of external hemorrhage, as well as hemorrhages from the air passages and gastrointestinal tract, in which blood leaves the body before destruction and reabsorption. Here, evidences of blood destruction will be lacking, but as long as adequate supplies of blood-forming materials are available, evidences of rapid red cell regeneration will be present. Therefore, the pictures for acute blood loss and chronic blood loss will be different

(a) *Acute blood loss* The deficiency in red cells and hemoglobin will not be apparent until increased plasma volume occurs. Compensation is by rapid regeneration from existing stores, so the evidences of increased bone marrow activity (reticulocytosis, polychromatophilia, nucleated red cells, neutrophilic leucocytosis, thrombocytosis) dominate the picture, and cells of normal size and hemoglobin content (normal color, volume and saturation indices) are formed as long as the supplies of stroma- and hemoglobin-building materials are not exhausted. Later, decreased color, volume and saturation indices may occur if the loss of blood was extreme, and decreased blood destruction (low icterus index, poikilocytosis) may occur as a compensatory factor; but these changes are never present in the first few days

(b) *Chronic blood loss* Here, the exhaustion of the hemoglobin-building (and probably also of stroma-building) material becomes the dominant factor, and this relative insufficiency gives rise to a picture almost identical with the absolute insufficiency (see 1 (a) above). Thus, evidences of compensatory decreased blood destruction and, to a less extent, of compensatory increased blood formation are both present, but the most characteristic change is a decrease in the color, volume and saturation indices, particularly the latter. Removal of the cause and administration of erythrocyte-forming substances are obviously both indicated. Here, too, it is possible for regeneration to keep pace with loss and, when the total blood volume and the normal rate of regeneration are considered, it is evident that the total quantity of blood lost per day must be very considerable (actual amount undetermined) to produce anemia, if no additional factors are present

DIFFERENTIAL DIAGNOSIS OF ANEMIAS

Unfortunately, clinical anemias are usually due to a combination of the above mentioned fundamental causes, and are in many instances too inadequately studied for one to be certain which of these factors plays the major rôle

In this study much material was accumulated to aid not only in the differential diagnosis of anemias but likewise in the determination of the fundamental factors responsible. It has seemed best to summarize these in tabular form since detailed presentation would exceed the space limits of

a journal article. Therefore, we have grouped, in the table, the chief diagnostic points in the more important clinical conditions in which the differential diagnosis of anemia arises. The figures* given in the table are based in part on our own experience and in part on a study of the literature. This literature is so extensive that space limitations prevent reference to all the articles consulted. Many of them will be found in the bibliographies given by Ordway and Gorham,⁹ but our files contain many articles on anemia and related subjects which they have not included.

The plan of the table is as follows. At the top are listed the data which it is most important to secure in differentiating anemias. Those tests followed by the letter A should be determined in every case in which anemia is considered. Those followed by B should be determined in almost every case. Those followed by C are less frequently of value and may be omitted except in the more puzzling cases, while those followed by D are still less frequently of aid in the differential diagnosis. Still other tests, such as cultures, platelet counts, and determinations of coagulation time, bleeding time and clot retraction time, will occasionally be desirable. The numbers in the first column are simply for reference. The second column

starts with normal men⁷ and women,⁸ the findings in whom serve as a basis for comparison. These are followed by twenty-eight conditions which must be considered when studying a patient thought to have anemia. This list could doubtless be extended, but includes the more important conditions. Note that the first sixteen are all characterized, as a rule, by color, volume and saturation indices within the normal range. The next group (17 to 20, inclusive) are sharply differentiated from the others by the high color and volume indices with normal saturation indices. The third group (21 to 23, inclusive) are characterized by a marked tendency toward a decrease in all three of these indices, and this is the only group in which a low saturation index occurs. The final group (24 to 28, inclusive) often have normal indices, but may show low color and volume indices. The numbers in the column headed "Relative Frequency" are in the approximate order of decreasing incidence, i. e., the conditions numbered 1 to 10 are very common, 11 to 20 are less common, and those above 21 are rare. In the remaining columns, an effort has been made to give, whenever possible, actual figures which will include approximately 95 per cent of the cases of each condition. The usual finding in a particular condition will, therefore, be intermediate between the extremes recorded.

In the column headed "Therapy," only the most specifically beneficial treatment is indicated and thus in the briefest possible form. Thus "liver" is meant to include not only liver itself, but liver extracts, desiccated stomach, and all nuclear material which has been shown^{11,12,13} to be effective in produc-

*An improved method of reticulocyte staining¹⁴ has been developed since the manuscript was submitted for publication. With this method the normal values are from 0.5 to 5.0 per cent, with an average of 1.5 per cent, and the average counts in the anemias will be about three times as great as would be inferred from the figures in the table.

ing a specific reticulocyte increase in patients with pernicious anemia. Similarly, "iron" refers not only to therapy with inorganic iron in large doses, but to therapy with all the known hemoglobin and stroma-building substances.² The large variety shown in this list of most important therapeutic procedures demonstrates incontestably the extreme importance of accurately determining the cause of any anemic condition. To merely prescribe a little iron and arsenic because the patient is thought to have a "secondary" anemia, in the present state of our knowledge, borders on criminal malpractice, for the anemia may be due to a readily removable cause (intestinal parasites, chronic lead poisoning, focal infection, bleeding hemorrhoids, etc.) To give "liver" therapy to such cases without an effort to determine and to remove the cause is equally undesirable. Accurate diagnosis is absolutely essential to adequate therapy.

The remainder of the table is largely self-explanatory, but a few points require comment. Obviously, the list of causes of acute and chronic hemorrhage and dietary deficiency anemias is very incomplete, while the individual subdivisions of the intestinal parasite, poisoning and infectious type anemias are not given. They should, however, readily suggest themselves to any well-trained physician. Note that the essential difference between acute internal and external hemorrhage is that, in the former, evidences of internal blood destruction appear within a few days, i.e., increase in the icterus index and in urobilinogen excretion. This may aid as well in differentiating cerebral hemorrhage from thrombosis or embolism, in differentiating hemor-

rhage from shock, ruptured ectopic pregnancy from most other acute conditions, and in detecting hemorrhagic infarcts, etc.

Note that in sickle cell anemia there are evidences both of rapid red cell destruction within the body and of rapid red cell regeneration, suggesting the possibility that the peculiarly shaped cells are especially susceptible to normal erythrocyte-destroying mechanisms.

Other myelophthasic anemias (malignant tumors involving the bone marrow, osteomyelitis, etc.) show findings similar to those in myelogenous leukemia with the exception that the white cell count in these conditions seldom exceeds 50,000 and the numbers of promyelocytes and myeloblasts tend to be less. Roentgenograms of the bones will usually decide the diagnosis. In each of these conditions, it is probable that a high color and volume index may occasionally occur, but the vast majority show normal indices.

Observe that the aplastic anemia picture is entirely different from that of pernicious anemia, and that there is no reason for confusing them, if the cases are properly studied. In aplastic anemia, the evidences of internal blood destruction are absent until internal hemorrhages occur.

Hemolytic icterus (familial or acquired) is the only group in which the fragility test is of prime importance. Note the almost constant decreased resistance of the red cells and increase in the reticulocyte count. Probably erythrocyte destruction and regeneration do not proceed at so rapid a rate in any other disease. It is, also, the only disease in which the volume index does not give the same informa-

tion as is derived from the determination of the average erythrocyte diameter. Hence, both determinations should be made whenever this disease is suspected.

Observe how sharply the pernicious group of anemias (17 to 20, with an occasional case of myelophthisic anemia, 7) are separated from all other types by the high color and volume indices. Since pernicious anemia itself is relatively common and all other members of the group are uncommon such cases should be considered as pernicious anemia until proved otherwise. Note that a high color or volume index constitutes almost a specific indication for "liver" therapy.

It is important to keep in mind the fact that the pernicious anemia of pregnancy is rare, while other types of anemia are common in pregnancy. These have not been listed under a separate heading because it seems to the authors that most of the true anemias (disregarding the 10 to 20 per cent relative decrease in erythrocytes due to increased plasma volume in the last months) occurring in pregnancy can be placed in one of the other groups. It must not be forgotten that pregnant women are subject to most of the disease conditions to which non-pregnant women in a similar age group are susceptible and that they are hypersusceptible to some of them. It is probably true that due to the demands of the fetus for iron and other erythrocyte-building materials in the latter months of pregnancy, an anemia might develop on a dietary intake which would prove adequate for a non-pregnant woman, but the fact remains that this is a dietary deficiency anemia, giving rise to the same signs and symp-

toms and responding to the same therapy as in the non-pregnant woman. The tendency in pregnancy to pyelitis, nephritis, and other infections usually giving rise to anemia is well known.

Observe that most cases in the next group of conditions (21 to 23) are distinguished from all other types of anemia by the low saturation index. Low color and volume indices occur more commonly in these than in other conditions. Since, of these conditions, chronic hemorrhage alone is common, it seems justifiable to consider this as the most probable cause of an anemia in which the saturation index is below 0.85, until otherwise proved. Note that a low saturation index constitutes a specific indication for "iron" therapy and that administration of erythrocyte- and hemoglobin-building material may be expected to be of benefit in any anemia in which the color or volume index is low, while in other anemias such therapy is of very doubtful value.

The final group of anemias (24 to 28 inclusive) can be separated from group I only in the cases in which the color and volume indices are low. As a cause of anemia only the infection group is very common, for malignant tumors, in which ulceration (with secondary infection or hemorrhage) and bone metastases can be excluded, seldom cause anemia.

The most common cause of anemia is unquestionably infection. The mechanisms of the production of anemia in infection are probably chiefly bone marrow depression and internal blood destruction. In most infections, the evidence suggests that the former factor plays the predominating rôle. But in infections with organisms producing

a hemolytic toxin, the latter factor predominates. Unquestionably, the nature of the anemia varies with the type and virulence of the organism, with the location and extent of the infection, and with the condition of the hematopoietic system of the individual. It is probable that almost every infection, whether acute or chronic, has some anemia-producing tendency. This accounts for the fact that the so-called "normal figures" for hemoglobin and red cell count based on studies of hospital or dispensary patients who do not have the commonly recognized causes of anemia are consistently lower than figures based on studies of perfectly healthy persons.

Note that many of these conditions may co-exist with red cell counts and hemoglobin estimations within normal limits, that in myelogenous leukemia an actual erythrocytosis sometimes occurs, and that the lower limits of the counts and hemoglobin estimations are very variable in the different conditions. We have studied the blood of many pernicious anemia patients within a few hours of death and find the red cell counts usually between 400,000 and 800,000 and the hemoglobin between 1.5 and 3.0 gm per 100 cc. We feel certain that these figures represent the lower limits compatible with life. Hence, the figures of 143,000 reported by Quincke and of 138,000 reported by Naegeli were probably due to errors in technique.

The reader may make many other deductions from a study of the table. In individual cases, it must not be forgotten that two or more of these conditions may co-exist.

It is obvious that any theory of the etiology of pernicious anemia must ex-

plain the relationship to achlorhydria, the evidences of increased rate of red cell formation and red cell destruction, the large size of the circulating red cell, the occurrence of similar blood pictures in some cases of sprue and pregnancy, and the therapeutic value of liver, kidney, stomach, nucleated red cells and extracts of these tissues. The common factor in the effective therapeutic material would seem to be relative richness in nuclei. An hypothesis which might explain this syndrome is the following. In the nuclei of most mammalian organs and tissues there exists a substance which is necessary for the development of mature erythrocytes of normal size and resistance to the wear and tear of circulation and to the normal mechanisms for the destruction of red cells. The normal gastric secretion is capable of liberating this substance from skeletal muscle (meat) and other sources. In the common form of pernicious anemia, there is associated with the achlorhydria a deficiency of the digestive activity which liberates this effective substance. A deficient supply of this substance results in the formation of large cells by the bone marrow which are destroyed with exceptional readiness in the blood stream. This rapid destruction leads to the increased icterus index, to the increased excretion of urobilinogen in stools and urine, to the increased stores of iron in the liver and the spleen with resultant enlargement of these organs, and to the anemia. The anemia serves as a stimulus to more rapid red cell regeneration, giving rise to the tendency for nucleated, polychromatophilic and reticulated red cells to appear in the blood stream in increased numbers,

thus completing the hematologic picture of this disease. Organs rich in nuclei contain enough of this substance (probably not nucleoprotein or nucleic acid, but either a digestion product of these substances or something associated with them in the nucleus) in readily available form so that ingestion in large amounts gives an adequate supply even in the absence of the digestive substance. In sprue, the failure is probably in absorption (due to diarrhea) of the substance after liberation by digestion, while in the pernicious anemia of pregnancy, it is possible that there is a relatively insufficient intake of the substance to supply the needs of both the mother and the fetus.

SUMMARY

A table showing the results of the most important examinations in the different types of anemia is given, together with a discussion of the fundamental causes of anemias and the differential diagnosis of clinical anemias. A theory of the etiology of pernicious anemia is advanced.

CONCLUSIONS

1 The term "secondary anemia" should be discarded as it is not sufficiently descriptive and anemias formerly grouped together under this

term differ widely in etiology, symptomatology, blood findings, and in response to different types of therapy.

2 An accurate diagnosis of the etiology is essential to the proper treatment of anemias. To facilitate this differential diagnosis, a table is presented which gives the more important laboratory and clinical findings with the chief therapeutic indications in twenty-eight of the more important conditions which may cause or be confused with anemia.

3 A cause for anemia may exist without the development of actual anemia, since it is possible for blood regeneration to keep pace with blood destruction or with hemorrhage.

4 There are only three fundamental causes of anemia, i.e., deficient formation of red cells or hemoglobin, excessive destruction of red cells or hemoglobin within the body, and loss of red cells and hemoglobin from the body. These deserve more thorough study than they have previously received.

5 Clinical anemias should be studied with the object of determining what is the relative part played by each of these fundamental factors in any individual case. Criteria to use in this evaluation are indicated in this paper.

A Comparative Study of the Use of Whole Liver, Liver Extract and Ventriculin*†

By HUGO A. FREUND, A.B., M.D., F.A.C.P., and ALVIN E. PRICE, A.B., M.D.,
Detroit, Michigan

THE use of various anti-anemic substances in the treatment of primary anemia is now well recognized and established in medical therapeutics. Although sporadic cases have appeared in the literature in which some form of liver therapy has failed, there is abundant evidence which demonstrates the undoubted value of anti-anemic substances. As to their comparative value, however, there is relatively little to be found which indicates any difference in response to them. Thus, Minot and his co-workers¹ report that they noted no difference in the reticulocyte response obtained in the feeding of either whole liver or liver extract. Ordway and Gorham² treated nineteen cases with liver and six with liver extract, and from their study concluded that both groups responded equally well. Davidson et al.³ arrived at a similar conclusion. In a discussion on the use of "Desiccated Stomach" in the treatment of pernicious anemia, Isaacs and Sturgis⁴ stated that they were unable to find a difference in the course of the remission, or in the response of the

neurologic lesions, with ventriculin therapy as compared to that found with the use of liver. Conner⁵ was also of the opinion that the results of treatment with "swine stomach" would compare favorably with those derived from the use of liver or liver extract.

Quite in contrast to the above studies are those of Schulten⁶ and Berglund et al.⁷, in which no hemopoietic response with liver extract was found, but in which a definite remission resulted with the use of fresh whole liver. The case study reported herein bears a striking resemblance to the above group except that in addition to the whole liver and liver extract used above, ventriculin (Parke, Davis & Company) was also among the preparations administered.

The patient under discussion had been under our observation on two previous occasions, and at both times was successfully treated with liver extract. At the time of his third admission to the hospital, he was in a state of relapse with a marked anemia. The administration of ventriculin, and later the use of liver extract, failed to produce any significant remission in the blood picture. It was not until the patient was given the juice of whole liver that a satisfactory erythropoietic

*From Department of Internal Medicine, Harper Hospital, Detroit, Mich.

†Received for publication, September 17, 1931.

response on the part of the bone marrow was obtained. Because of the rarity of such a comparative study in the same individual, and because of the unusual nature of the results obtained, it was thought advisable to report the case study in the hope that it might offer some aid in the treatment of those cases which appear refractory to the usual anti-anemic therapy

CASE SUMMARY

First Observation The patient, O B, male, aged 20, was first seen on the medical service in March, 1929. At the time of his first admission he complained of weakness, loss of weight, sore tongue and paresthesias of the hands and feet. Examination at that time revealed an emaciated, pasty appearing boy with a ptosis of the left eyelid, a corneal scar in the left eye and an atrophy of the tongue. The heart was negative except for an apical systolic murmur. The spleen was enlarged to about two fingerbreadths below the costal margin and was firm and tender. There were no objective neurological findings.

The blood picture was that of a primary anemia with hemoglobin, 65 per cent, red blood cells, 1,710,000, white blood cells, 9,150. The differential count revealed 76 per cent polymorphonuclears, 16 per cent lymphocytes, and 8 per cent mononuclears. Red cells showed anisocytosis and poikilocytosis. Gastric contents showed no free hydrochloric acid. The indirect Van den Bergh was slightly positive.

On the basis of the above findings a diagnosis of pernicious anemia was made and liver extract therapy instituted (vials IV—daily, equivalent to 400 gms fresh raw liver). As a result of this treatment the patient had a prompt, though comparatively small, reticulocyte response (56 per cent) and a very definite increase in the percentage of hemoglobin and in the number of red blood cells. Five weeks after the institution of the liver extract therapy, the hemoglobin rose to 85 per cent and the total red count became 4,000,000. Coincident with the remission in the blood pic-

ture, the patient gained weight and his symptoms disappeared.

During the following ten months he remained symptom free on one quarter pound of liver a day with occasional substitution of liver extract. At the end of this time, he became unable to purchase liver and as a result some of his former symptoms returned. His blood picture, however, remained normal (Abortive relapse of Isaacs⁸).

Second Observation During the second period of observation there was little in the general physical and laboratory findings which differed from those present at the time of the patient's discharge from the hospital ten months previously. After only a brief period of hospitalization his symptoms disappeared and he was again discharged on one vial of liver extract, three times daily.

For the following six months the patient continued on liver extract and remained in perfect health. At the end of this time, however, he became financially unable to purchase liver extract, and as a result he took no anti-anemic substance. During this time he lost weight, became weak and developed numbness and tingling of the hands and feet. In addition to this, he complained of nausea and vomiting. With these symptoms he re-entered the hospital.

Third Observation Physical examination on his third entrance to the hospital revealed little that was not found at the time of his first admission. There was obvious pallor and evidence of considerable weight loss. The ocular findings were as before and the atrophy of the tongue was still in evidence. The spleen was enlarged to the same extent as formerly but appeared to be less tender to palpation. There was no disturbance in the vibratory, or motion and position senses in the extremities. Reflexes were normal. Heart and lungs were negative.

Laboratory Data Blood count: Hemoglobin, 50 per cent, red blood cells, 2,500,000, color index, 1.1, white blood cells, 4,000, polymorphonuclears, 39 per cent, lymphocytes, 60 per cent, eosinophils, 1 per cent. Red cells showed poikilocytosis, anisocytosis and polychromatophilia. Diameter of red cells varied between 9.5 and 4

μ Reticulocytes, 0.4 per cent Blood fragility, beginning hemolysis, 0.4 per cent, complete 0.3 per cent Hematocrit study volume percentage of RBC = 29 Blood culture and blood Wassermann, negative Blood nitrogen, 28.6 mgs Blood sugar, 0.100 per cent Blood cholesterol, 143 mgs Blood platelets, 383,000 Bleeding time, four minutes Coagulation time, four and one-half minutes Van den Bergh, direct and indirect, negative Gastric analysis (with histamine), no free hydrochloric acid (three examinations) Urinalysis, negative Urobilinogen, positive Stool analysis, normally formed, no blood, ova or parasites X-ray examination gastro-intestinal, negative, chest, negative except for extensive root deposit with exaggerated trunk markings throughout both lung fields

CLINICAL COURSE

First Period During the first eighteen days of hospitalization the patient was given ventriculin (Parke, Davis & Company), the initial dose consisting of three vials daily, (30 gms) At the end of ten days the dose was increased to four vials, this being continued for eight days Because of persistent nausea and vomiting, an attempt was made to give this preparation by rectum (Vials VI, 60 gms), but this was unsatisfactory

During the period of ventriculin therapy there was no clinical improvement The nausea and weakness persisted The blood picture showed no appreciable change, the reticulocytes increasing to 0.9 per cent and the total red count reaching its highest peak of 2,500,000 on the tenth day, this representing a total gain of only 250,000 red cells The hemoglobin dropped from the original 50 per cent to 38 per cent on the eighteenth day The white count remained low throughout, the differential showing a constant lymphocytosis, on one occasion reaching 86 per cent The polymorphonuclear cells showed an almost constant shift to the left While the total blood count showed little or no change, a study of the blood smear revealed evidence of attempts at blood regeneration, i.e., stippling of red blood cells, normoblasts, etc

Throughout the entire period of ventriculin therapy the patient had a daily

temperature elevation varying from 99 to 100 Careful and repeated urinalyses, sinus and chest x-rays, etc., failed to reveal any evidence of infection or other cause for this febrile reaction

Second Period During the second period the patient was given liver extract (Lilly's No 343, one vial = 100 gms whole liver) starting with four vials a day and after two weeks increasing this to six vials daily The latter dosage was given for one week While under this therapy the blood picture showed little change The reticulocytes rose from 0.3 per cent at the beginning of the period to a maximum of 1.14 per cent on the eleventh day The red cell count increased from 1,230,000 to 2,020,000 on the sixth day, and then fell to 1,895,000 The hemoglobin increased from 38 to 48 per cent over the entire period of three weeks The leucocytes remained low throughout, only on one occasion reaching as high as 8,100 The blood smear showed evidence of blood regeneration with a tendency to a right shift of the leukemoid picture Throughout this period also, the patient continued to have an unexplained daily temperature elevation, although the general level was below that of the preceding period The general condition showed no appreciable improvement

Third Period Following the unsuccessful use of liver extract, first of three and then of six vials a day, the patient was next given the juice of one pound of whole liver daily The following day the reticulocyte count rose from 0.33 per cent to 0.5 per cent and on the third day it rose to 9 per cent The red count increased from 1,900,000 to 3,000,000 on the eighth day, the leucocyte and differential count remaining practically normal throughout The smear showed evidence of progressive blood regeneration

On the fifteenth day of "liver juice therapy" it became obvious that the patient had reached a standstill in his blood picture The hemoglobin had attained a level of 78 per cent and the red count had already started to drop slightly The juice of three pounds of liver was then given daily with a resulting progressive increase in the hemoglobin and red count On the seventh day the hemoglobin rose to 92 per cent and the red count reached 4,720,000 The rest

of the blood count was normal—the smear presenting a normal blood picture

Coincident with the elevation in the blood count there occurred a distinct improvement in the clinical condition. Appetite became progressively better, nausea and vomiting ceased, and strength returned. The temperature elevation persisted.

An attempt to decrease the dose of liver juice to that of two pounds daily, resulted in a prompt drop in the blood count and a recurrence of a characteristic group of symptoms, viz, numbness and tingling of fingers and stiffness of the neck. This picture was seen on several subsequent occasions during a relapse in the blood picture. Because of this the dose was increased to its former level with a resulting prompt improvement in the blood picture and in the clinical condition of the patient.

Realizing the impracticability of taking whole liver juice after leaving the hospital it was thought advisable to try some preparation which would be more conveniently used by the patient. Although liver extract had previously failed it was tried again hoping that it would maintain the blood level produced by the whole liver. The use of three vials a day was promptly found to be inadequate, and the dose was therefore increased to six vials. This resulted in a prompt return of the blood picture to its former level. Two weeks later it became necessary to increase this to eight vials daily because of a drop in the blood count and a return of the above described symptoms so characteristic in this case of a falling blood picture. This proved to be adequate for only two weeks, and at the end of this time the clinical condition of the patient again started to fail. Because of this the liver extract was supplemented by whole liver (one-third pound daily), this resulting in prompt improvement in the general condition. After one month on this "combined therapy" the liver was omitted from the diet entirely. Ten days later the amount of liver extract was decreased to six vials without any change in the blood picture or in the clinical condition of the patient. At the present writing this dosage has been further reduced to three vials a day. The blood count at

present is hemoglobin, 97 per cent, red blood cells, 5,120,000 (on three vials a day for two weeks).

[It has subsequently come to our attention that this patient had another relapse during which he was cared for in the Simpson Memorial Institute for Medical Research, Ann Arbor, Michigan. While in this institution he was successfully treated with intravenous liver extract after the use of stomach and liver preparations by mouth had failed.]

COMMENT

In a review of the above case study several facts are worthy of note. One is impressed with the successful use of whole liver after both liver extract and ventriculin failed. There is also noted the necessity for large and increasing doses of anti-anemic substances in order to obtain the desired blood level.

The first observation is of particular interest in this case when it is recalled that the patient under consideration had previously responded well to three vials of liver extract a day, and even at the present time is satisfactorily controlled on similar quantities of the same preparation. In the absence of complicating factors such as infection, etc., it is thought that such a variation in response at different periods can best be explained on the basis of a different reactive state of the bone marrow during the various remissions.

The reason for the success of whole liver in this case after the other products had failed is not at once apparent although several explanations suggest themselves. One might first question the potency of the products used. The ventriculin was supplied by the manufacturers, Parke, Davis & Company, for experimental purposes. The liver extract used was the standard

product of Eli Lilly & Company (No 343)

A second explanation lies in the possibility of an inadequate dosage of these products. Unfortunately, the administration of larger quantities of ventriculin was prevented by the patient's persistent nausea and vomiting. Final conclusion, therefore, should not be drawn regarding the efficacy of this product in this case since only the minimum amount could be used. It will be noted, however, that the usually required dosage was administered without success. A significant elevation of the reticulocyte count did not occur. With liver extract, although a definite reticulocytosis was produced, the administration of nearly twice the quantity ordinarily required was insufficient to produce any appreciable increase in the red blood cell count. In contrast to this, the use of proportionately less fresh whole beef liver as liver juice, was sufficient to produce not only the same reticulocyte response as that resulting from liver extract, but a definite elevation of the total red count and percentage of hemoglobin as well.

A third explanation, i.e., the presence of an infection, is suggested by the persistent fever and the "left shift" of the neutrophilic elements of the blood. That an infection may alter the response of the blood-forming organs to anti-anemic substances is illustrated in the recent case report of Smithburn and Zerfos⁹. In an earlier publication by Minot, Murphy and Stetson¹, the depressant action of infections on bone marrow was also emphasized. In this case, as already stated, no focus of infection could be found. *Of further importance in this*

connection is the fact that the fever was not confined to the period of ventriculin and liver extract therapy, but continued throughout the administration of whole liver juice as well.

The failure of the above suggestions to account for the results in this case, leads one to suspect that the explanation may lie in the composition of the whole liver in contrast to that of liver extract or ventriculin. The question, therefore, arises—does whole liver contain some principle not present in either of the other two substances, or present in lesser quantity, which renders it more effective in its action on the hemopoietic system when the latter is in a state of marked depletion? That some difference does exist between the effect of these various substances on blood-forming tissue is suggested by the eosinophilia resulting from the use of whole liver in contrast to the absence of this response with the use of liver extract (Meulengracht and Holm¹⁰ and others^{11,12}). The absence of this effect with ventriculin has also been noted (Goldhamer¹³). Likewise, the special effect of whole liver on hemoglobin formation as compared to that resulting from the use of liver extract is further evidence of the difference of effect of these substances (Isaacs, Sturgis and Smith,¹⁴ and others¹⁵). To explain a variation in erythrocytic response on the same basis is, of course, conjectural, but would nevertheless appear worthy of consideration.

The second observation mentioned above in which it was noted that larger quantities of anti-anemic substances were required for adequate stimulation of the bone marrow has already been noted by others. Thus

Minot and his co-workers¹ were able to produce a secondary reticulocyte response together with a marked increase in the total red cell count after feeding larger quantities of liver pulp. In our case there developed a secondary reticulocyte response immediately upon the administration of fresh whole liver juice and simultaneously with this, a definite elevation in the total red count and percentage of hemoglobin. Further increase in the amount of liver was then required to attain the maximum blood level desired. As already stated in the discussion of the case early attempts at decreasing the quantity of whole liver as well as substituting liver extract for the latter were unsuccessful in maintaining the desired blood picture. It was not until two and one-half months after the institution of liver therapy that substitution by liver extract became possible. Such an observation as this, in the absence of complicating factors, would lead one to postulate that the response of the

bone marrow in some cases, and at certain periods, is dependent upon the "quantity" of the anti-anemic substance administered as well as the "quality" as already discussed above.

SUMMARY

A case of primary anemia is presented which failed to respond to both ventriculin and liver extract, but which later responded satisfactorily to the juice of whole liver.

Attention is also drawn to the fact, that larger and increasing doses of anti-anemic substance were required to produce and maintain the desired blood level.

It is suggested that in those cases which prove resistant to the usual "anti-anemic extracts", whole liver be given a trial. It is further suggested that large quantities of the anti-anemic substance be given before the case be considered refractory.

We wish to thank Mr. Emil Schleicher of Parke, Davis and Company, for his technical and material assistance in the study of this case.

If You Have a Persistently High Blood Pressure

“IF YOU have passed the milestone of middle life, you should develop a hobby of some type, which is interesting, pleasant, and not a part of your daily employment or thought. Secondly, you should teach an understudy, if you are in business, to take charge of your affairs from time to time, so that when that day comes when you should play a less active rôle in the management of your affairs than formerly, it will lessen that inevitable anxiety which will confront you when you realize that your endurance and physical fitness are becoming less.

“Finally, if you represent that large group of despondents who have high blood-pressure disturbances as a part of their general body let-down, allow me to say a word of cheer. If your body were a mechanical thing, manipulated by a motor, with bearings and joints that were dependent upon protection, adjustment, and lubrication in a manner similar to that of the automobile, and if life's journey were traveled along a rough and rugged road which ended in precipitate heights, and you wished to reach life's goal of matured years, you could do any one of the following three things: Lighten your daily loads, protect the wear and tear of your machinery, or smooth out the roadbed.”

(From *How's Your Blood Pressure?* by CLARENCE L. ANDREWS, M.D., F.A.C.P., The Macmillan Company, 1931.)

Raynaud's Disease Affecting Men*†

By EDGAR V ALLEN, M D, F A C P, and GEORGE E BROWN, M D, F. A C P,
Rochester, Minnesota

OF the vasospastic disorders affecting the peripheral circulation, of which Raynaud's disease represents the most typical form, the distribution by sex is the reverse of that found in organic disease of the peripheral arteries.² Various writers have given the incidence of Raynaud's disease in the female as from 60 to 90 per cent, and a critical survey of the reports of cases offered as examples of Raynaud's disease in the male has given evidence of an exceedingly high proportion of erroneous diagnoses.¹ Many such cases represented classical examples of thrombo-angitis obliterans.

The criteria for diagnosis of Raynaud's disease are as follows (1) episodes of change in color, of the vasospastic type, excited by cold or emotion, (2) bilaterality, (3) presence of normal pulsations in the palpable arteries, (4) absence of gangrene, or its limitation to minimal grades of cutaneous gangrene, (5) absence of any primary disease which might be causal, such as cervical rib or organic disease of the nervous system, and (6) symptoms of two years or of longer duration.

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota

†Submitted for publication, December 9 1931

The first four criteria were succinctly stated by Raynaud.¹ The fifth and sixth have been added by us to emphasize the necessity of eliminating causes to which the vasomotor symptoms might be secondary.

PRESENT STUDY

A diagnosis of Raynaud's disease, uncomplicated by scleroderma or trophic changes, and unassociated with arthritis, has been made in 150 cases at The Mayo Clinic. The characteristic symptoms of vasomotor episodes of discoloration of the skin of the fingers or toes, occurring bilaterally and intermittently, were present in every instance. Males comprised seventeen of these 150 cases (12 per cent), but in only seven of these seventeen (5 per cent of 150) could the diagnosis be substantiated on the basis of additional requirements of long duration of symptoms and of demonstration of absence of such conditions as cervical rib, and organic disease of the peripheral arterial system.

In each of the remaining ten cases (table) the diagnosis "probable Raynaud's disease" was made, in each instance some objection could be offered to the diagnosis of true Raynaud's disease. These objections are as follows: in cases 1 and 8 the duration of symptoms was only four and

six months, respectively, in case 2, rudimentary cervical rib was demonstrated roentgenologically although it probably was not of significance, in cases 3, 4, 5, 6, 7, 8, 9, and 10, specific notation as to presence of pulsation was lacking, and in case 6, there was no notation as to the duration of symptoms. Gross evidence of obstructive arterial disease was not present in any of the cases. However, in those cases in which there was no specific mention of pulsations in the peripheral arteries, the possibility of the presence of arterial disease characterized by occlusion cannot be excluded.

In seven of the seventeen cases (41 per cent) there was evidence of functional or neurotic disturbances, such as dizziness, nervousness, flatulence, vague gastric distress, biologic inferiority, or cardiac neurosis. The incidence of these disturbances exceeds by 17 per cent that found in a group of females with Raynaud's disease.

The ages of sixteen of the patients at the onset of symptoms were as follows: first and second decades of life, eight cases; third decade, three cases; fourth decade, five cases. In the remaining case the age at onset of the symptoms was not known. This emphasizes the fact that Raynaud's disease is a condition of youth and middle age. In a series of 115 females with uncomplicated Raynaud's disease, 77 per cent of the patients manifested their first symptoms before the age of forty years.

Data on height and weight were available in fifteen of the seventeen cases. Comparison with standard tables based on age and height and allowing a variation of plus or minus 10 pounds, disclosed that three of the

patients (20 per cent) were overweight, seven (47 per cent) were of normal weight, and five (33 per cent) were underweight. In this small series of cases, such a distribution is probably of no significance. For comparison among women with Raynaud's disease, the thin, asthenic type of person is more frequently seen, of 112 women, 50 per cent were underweight, 35 per cent of normal weight, and 15 per cent of more than normal weight.

Forty-seven per cent, eight of the seventeen men, were unmarried. For comparison 40 per cent of 121 women with the same type of Raynaud's disease were unmarried. The comparative youth of a number of the male patients doubtless accounts for their being unmarried.

COMMENT

A convincing explanation of the low incidence of Raynaud's disease among men, as compared with women, has not been offered. Equally as difficult of explanation is the comparatively high incidence (98 per cent) among men² of thrombo-angitis obliterans. Considerable weight in diagnosis can be given to the predilection of these two diseases for the respective sexes. If a novice in the diagnosis of peripheral vascular diseases were shown 100 women and 100 men known to be affected with either Raynaud's disease or thrombo-angitis obliterans, he could arrive at the correct diagnosis in 90 per cent of the cases with no further knowledge than that of the sex of the patients. The presence of the other 10 per cent, however, emphasizes the necessity of careful development of the clinical history and of examination with assiduous attention to details.

Our studies have indicated that men

* Denotes normal pulsations in the radial, ulnar, dorsalis pedis, and posterior tibial arteries

** Denotes no information regarding pulsation

*** Denotes normal pulsation in the radial artery and no information regarding pulsation in the ulnar, dorsalis pedis, and posterior tibial arteries

are particularly subject to organic derangement and women particularly to functional derangement of the peripheral vascular system. Whether this is because men and women live and work at different paces, whether the reason is that women secrete a protective hormone denied to men, or whether the explanation lies in the different tendency of members of the two sexes to acquire diseases of which neurosis is an element is not known.

SUMMARY

The condition of seven men met all the requirements for a diagnosis of

Raynaud's disease. In an additional ten cases, the diagnosis was probable Raynaud's disease. Of all patients affected with uncomplicated Raynaud's disease, about 5 per cent were men (seven cases of 150). In an additional 7 per cent of uncomplicated cases, also (ten cases of 150), the patients were men, in this 7 per cent of cases, the diagnosis seemed warranted but some objection could be raised to it. Possible reasons for the predilection of peripheral vascular diseases for one or the other of the two sexes are mentioned in the paper.

Does Liver Therapy Benefit the Diabetic?*†

By ELMER L. SEARINGHAUS, M D, F A C P, *Madison, Wisconsin*

AS a consequence of the reports of Blotner and Murphy¹ a number of trials have been made in this hospital with liver therapy for diabetes mellitus. The first of these was made with feeding of whole liver, 180 grams daily, to two cases of clinically unvarying tolerance. The results gave no encouragement at that time (1929). In July, 1930, our attention was directed to the possible merits of a mixture of an extract of horse liver, horse blood, with hypophosphites, alcohol, and saccharin, referred to below as "liver mixture". The manufacturers of a certain commercial horse liver and blood mixture had reports from two clinicians that this preparation had apparently been of marked benefit to some diabetic patients. This mixture has been prepared and marketed for the treatment of anemias other than pernicious anemia. Consequently the manufacturers prepared the special mixture described above, omitting the sugar and glycerol from the usual commercial formula. Late, on request they supplied also simple aqueous liver extracts, preserved with 16 per cent alcohol, and dried residue from aque-

ous liver extract. Since careful clinical records were not available from the clinicians who had first reported on the ordinary mixture, they were eager to have dependable studies of such products made before any attempt was made to enter into commercial production. These materials were made under the personal supervision of the chemist at the packing plant. The commercial use of meat from the horse has been developed to a large extent by this firm, both for foreign trade and for the production of compounded rations for small animals in this country. The selection of animals and the plant conditions are apparently excellent. This report therefore applies entirely to the use of material from the liver of the horse.

The first patient studied was a 15 year old girl who had been diabetic for four years. She required 105 units of insulin daily with a maintenance diet. An attempt was made to replace insulin with "liver mixture", but a precomatose condition was apparent in 24 hours after insulin withdrawal. A few days later an attempt was made to reduce the insulin dose by substituting the oral preparation for 20 units of insulin. When 85 units were combined with 15 c c of "liver mixture" before each meal for one week there was no evidence of benefit. An increase to 30 c c three times daily was

*From the Department of Medicine and the Wisconsin General Hospital, University of Wisconsin, Madison, Wisconsin.

†Received for publication, August 10, 1931.

no better After a nine day interval a simple aqueous liver extract was tried for seven days without benefit Thereupon a liver press juice was substituted for six more days. Throughout this period 95 units of insulin were administered daily, in spite of which there was slight ketosis and glycosuria as marked as when insulin was given alone.

At the same time a young man was treated with "liver mixture" as soon as it had been found that on a standard 1525 calorie diet he excreted 14.4 to 16.5 grams of sugar daily With the use of 30 c c of the oral preparation before each meal for three days his glycosuria rose to 23.8 to 27.5 grams, with unabated ketosis With the use of 30 units of insulin daily he was free from glycosuria and ketosis while using a 2270 calorie diet

An emaciated diabetic man of 40, weighing 100 pounds, was found to maintain his weight on a 1965 calorie diet While using 10 units of insulin daily he had only traces of glycosuria, with infrequent positive nitroprusside tests on the urine Blood sugar values of 187 to 199 mg per 100 c c were observed in the morning Addition to this routine of "liver mixture" in doses of 15 c c three times daily for five days, then of 30 c c before each meal for six days, was ineffective There were no consistent changes in glycosuria, weight, or the level of blood sugar Ketosis did not occur during the last week of this trial, but it was absent except for three days in the following three weeks when insulin alone was used at the same level as before

A 57 year old man with dry gangrene of several toes was found to lose 14.7 to 18.2 grams of sugar

while on a 1525 calorie diet There was no ketosis The use of "liver mixture", 15 c c before meals for six days, was followed by an apparent improvement, with glycosuria less than six grams on four of the six days Use of the simple extract of liver in 15 c c doses for five days, in 30 c c doses for three days, and of the liver press juice in 30 c c doses for five days gave similar results When only the diet was used as treatment the result was just as good, with glycosuria continuing to vary from 3 to 8 grams daily During the period of observation the morning blood sugar had dropped from its original level of 200 mg to 80 mg six days after stopping liver press juice The use of insulin in two doses of 5 units each abolished all glycosuria This case had evidently made the usual improvement in sugar tolerance which must be attributed to dietary restriction alone The liver treatment cannot be considered responsible for even this slight improvement

It was considered possible that absorption of some insulin given by mouth might be facilitated by liver materials in a way similar to that claimed by Stephan² Therefore a trial was made by mixing insulin in a solution of the liver and blood extracts only, the materials used for making the "liver mixture" The patient was a male, aged 33, who required 52 units of insulin to remain free from glycosuria and ketonuria on a 2270 diet When the insulin was given in the tissue extracts by mouth, the dose and time being the same, glycosuria reappeared The insulin doses were doubled without any benefit The loss of sugar was similar

during the periods with such therapy and during intervals when only the liver and blood extract were administered, or for two days without therapy. A return to the use of 52 units of insulin promptly restored the balance of the patient. There is no reason to conclude that the insulin given by mouth to this patient had any effect.

Following this series of negative results it was thought best to try an exact duplication of some of the work reported by Blotner and Murphy.¹ An aqueous extract of liver was heated to 80°C, and the precipitated material was dried in an air current of 40° to 50°C. This treatment is said by the above authors to leave the activity of their preparations unaffected. The dry material from one pound of liver was estimated to be 24 grams. The use of 8 grams of this powder with each meal was easily arranged, this should be the equivalent of the ingestion of one pound of liver daily so far as the substances in such a preparation are concerned.

A male patient, aged 23, using 1965 calories and 35 units of insulin had slight morning glycosuria, minimal amounts of acetone in the urine, and his blood sugar was 143 and 140 mg on two mornings. The use of 24 grams of dried liver powder as above made no change in the urine findings, the blood sugar after two days was 136 mg in the morning, there were no insulin reactions.

Another patient, aged 14, required the same insulin dose and the same diet, but had no traces of acetone in the urine. In this case the insulin was withheld and the 24 grams daily of liver powder administered. Glycosuria and ketonuria reappeared and the

blood sugar rose from 120 mg to 167 mg. The liver powder was continued and the insulin doses were raised gradually. Not until after two days on the original dose of 35 units was the glycosuria and ketonuria abolished.

Further trials of this powder were made by giving it with the usual breakfast and insulin, following which series of blood samples were taken. On the preceding day a control observation was made. The protocols for two such cases are given in the table. It seemed in patient "M" that the blood sugar was less variable on the morning when the liver powder was given. The advantage is certainly not great. In the case of "A" the difference between the two curves is within the limits of variation commonly seen on successive days.

For the supply of materials as desired and for the cost of hospital study for these cases grateful acknowledgement is made to the Chapel Bros, Inc., of Rockford, Ill. Their chemist, Dr. A. E. Meyer, reports that he had made numerous attempts to detect activity of these and other liver preparations in rabbits, normal dogs, totally and partly depancreatized dogs, but without any convincing evidence of antidiabetic action.

We fail to find evidence that there is antidiabetic activity in the "liver mixture" or in the alcoholic extracts of liver and blood, liver alone, or in a press juice prepared from horse liver. A dried powder of the heat precipitate from aqueous liver extract was tried by methods similar to those used by Blotner and Murphy, but without any favorable result. No explanation is suggested for the failure to confirm the work of these authors, but the re-

sults reported agree with the negative results of dePencier, Soskin, and Best,³ Soskin, Binswanger, and Strouse,⁴ as well as of Root⁵

Primary Sclerosis of the Pulmonary Artery*†

Report of a Case

By EDGAR R. PUND, A.B., M.D., F.A.C.P. and THOMAS B. PHINIZY, M.D.,
Augusta, Georgia

ARTERIOSCLEROSIS of the pulmonary artery may be primary or secondary. The primary type is rare and affects the small arteries and the arterioles of the pulmonary circulation with or without accompanying arteriosclerotic changes in the larger branches. The sclerotic changes in the small arteries produce narrowing and even obliteration of the lumen, thereby causing an increase in the pulmonary blood pressure followed by dilation and hypertrophy of the right side of the heart and finally cardiac failure. There are no antecedent pulmonary or cardiac changes, and, according to Steinberg,¹ the use of the term primary sclerosis of the pulmonary artery is justified only when arteriosclerosis of the greater circulation is minimal or entirely absent.

Secondary sclerosis of the pulmonary artery is considered to result from mitral disease, cardiac abnormalities, emphysema, pleural adhesions, chronic bronchitis, or it may be incidental to a generalized arteriosclerosis.

In the periodical literature certain cases of sclerosis of the pulmonary

artery are referred to as Ayerza's disease. It is probable that some of these are primary and some secondary. The syndrome, Ayerza's disease, characterized by dyspnea, cyanosis, polycythemia and hypertrophy of the right heart, was described by Ayerza in 1901 in his lectures at Buenos Aires. He recognized the pathology of these cases as arteriosclerosis of the pulmonary artery, and spoke of the patients as "black cardiacs." Syphilis is considered a prominent etiological factor in this disease, but two opposing views are advanced with regard to the time of onset of the sclerosis, the discussion turning on whether the disease is primarily caused by the arteriosclerosis of the pulmonary artery, or whether the sclerosis is secondary to antecedent changes in the lung. In Ayerza's disease, Escudero² maintains that chronic syphilitic bronchitis is the first phase, characterized by polycythemia, and that the second phase presents, in addition, sclerosis of the pulmonary artery, peribronchial sclerosis and hypertrophy of the right heart. This view receives the support of Brachetto-Brain³ who thinks that the term, Ayerza's disease, should be restricted to cases in which each of the two phases is complete, the chronic broncho-pneumopathy with pro-

*From the Medical Department of the University of Georgia, Augusta, Georgia.

†Received for publication, August 10, 1931.

nounced polycythemia and the chronic cardio-angiopathy with insufficiency of the right heart. In a review of cases of Ayerza's disease, Cheney⁴ also states that a definite preliminary stage is apparently necessary for the final development. This essential antecedent is a chronic bronchitis of from one to twenty-five years duration; and Staffieri⁵ defines Ayerza's disease as a condition that occurs in young people or persons of mature age whose history reveals a bronchial affection, extending over a long period of time, accompanied by bronchopulmonary sclerosis and emphysema and a sclerosis of the pulmonary artery. The possibility of advanced secondary sclerosis should be borne in mind in considering cases of Ayerza's syndrome, because secondary sclerosis, while usually confined to the larger branches of the pulmonary artery, may in advanced cases affect the smaller arteries and give rise to the same symptoms that are produced by primary sclerosis.

Arrillaga,⁶ however, concludes that in Ayerza's disease, sclerosis of the pulmonary artery is primary and due to the *Spirochaeta pallida*, and that the arterial changes may or may not be accompanied by lesions in the bronchi and lungs, and that when lesions occur in the bronchi and lungs they are secondary to the sclerosis of the pulmonary arteries. Since Ayerza's disease is a term that has probably been used to designate both primary and severe secondary sclerosis of the pulmonary artery, it is probably better to distinguish cases as primary or secondary.

In the pulmonary artery arteriosclerotic changes of a moderate degree are not uncommonly seen at the nec-

ropsy table, incidental to a generalized arteriosclerosis or as a result of chronic cardiac and pulmonary lesions, and according to Warthin⁷ such secondary changes are without clinical significance. Cheney,⁴ Miller,⁸ and Rosenthal⁹ distinguish primary and secondary arteriosclerotic changes in the pulmonary artery, in the primary type the smaller arteries are affected and in the secondary type the medium-sized and larger vessels are involved. Hare and Ross,¹⁰ in a review of the literature on sclerosis of the pulmonary artery, admit the occurrence of sclerosis as a complication of some antecedent cardiac or pulmonary condition, but they have collected twenty-three fully reported and authentic cases of a group in which the signs and symptoms were due to alterations in the pulmonary arteries themselves and in which no antecedent cardiac, pulmonary or bronchial lesions were present. To this group they add one of their own. They emphasize in the primary type the occurrence of obliterative endarteritis of the small arteries which may be followed by dilation and atheroma of the larger vessels. Rosenthal⁹ considers primary arteriosclerosis of the pulmonary artery a definite clinical entity and in a study of three cases, he found the most pronounced changes in the small arteries with evidence of progressive changes to the medium-sized and larger vessels. Giuffrida¹¹ distinguishes primary arteriosclerosis with productive changes, with a tendency to obliteration of the lumen of the small arteries, from secondary sclerosis that results from hypertension in the pulmonary circulation. In primary sclerosis changes in the medium-sized and

larger arteries need not necessarily occur^{9,10,12}

From this review it is evident that there is general agreement that sclerosis of the pulmonary artery may be secondary to changes in the heart and lungs, as mitral disease, emphysema, pleural adhesions and chronic bronchitis and also may be incidental to generalized arteriosclerosis. When sclerosis results from these conditions it is the main trunk and larger branches that are affected by the usual arteriosclerotic changes, intimal thickening and degeneration, medial degeneration and dilation of the vessels. These changes are as a rule without clinical significance, or are overshadowed by symptoms that are produced by the primary disease.

There is also recognized, as an entity, primary sclerosis of the pulmonary artery, affecting the small branches and obliterative in type, and this form is frequently accompanied or followed by arteriosclerotic changes in the larger branches. This type of arteriosclerosis has been compared to the arteriosclerosis affecting the small arteries of the kidney.¹ Primary sclerosis of the pulmonary artery is rare and unless borne in mind can easily be overlooked clinically. It is more common in males and occurs in adults usually before the sixth decade. The changes in the arteries are responsible for the signs and symptoms, such as cyanosis, polycythemia, dyspnea, hemoptysis, and frequently somnolence, vertigo and heart pain, anasarca and passive congestion of the liver, spleen, kidneys, and intestines follow, dilation of the right side of the heart and usually dilation of the trunk of the pulmonary artery are evident. Cyanosis may precede the cardiac failure by

several years.^{9,13} The specific findings at necropsy are arteriosclerosis of the small pulmonary arteries with varying changes in the alveoli and the bronchi of a fibrotic nature, and dilation and hypertrophy of the heart, particularly of the right side.

The etiology is not clear. Syphilis is given the prominent rôle by many authors,^{2,9,10,12,14,15} but the possibility of damage due to the inhalation of gases and particulate matter is suggested by Rosenthal,⁹ and in a case reported by Staffieri⁵ the patient was a heavy smoker. Rheumatism may also be considered an etiologic factor. Von Glahn and Pappenheimer¹⁶ have described changes in the arterioles of the lungs in cases of rheumatism and they state that the healed lesions may develop a picture that simulates obliterative endarteritis. In a case reported by Steinberg¹ the symptoms of sclerosis were preceded by a severe rheumatic polyarteritis. Giuffrida¹¹ thinks that the arteriosclerosis of the pulmonary circulation is of a constitutional type.

For the purpose of clarity it is convenient to consider sclerosis of the pulmonary artery as showing the same types of sclerosis that are observed in the systemic arteries. Syphilitic mesarteritis has been described,^{7,17,18} and the changes in the pulmonary artery are identical with those seen in the aorta, affecting as they do the first part of the pulmonary artery. Ordinary atherosclerosis occurs in the pulmonary artery and involves the larger branches, it is usually secondary to cardiac or pulmonary changes or incidental to a generalized arteriosclerosis. And finally an obliterative endarteritis of the smaller arteries occurs, which may or may not be associated

with lesions in the larger vessels. This type is of importance because of the resistance offered to the pulmonary circulation. Cardiac failure follows.

CASE REPORT

The patient, a negro male, 40 years of age, was first admitted to the University Hospital, October 11, 1926. He was a tinner by trade and was not accustomed to hard manual labor. There was a history of gonorrhea but not of syphilis. There was no history of respiratory infections prior to the onset of the present illness. His first symptoms were those due to congestive heart failure, and set in four months prior to his admission to the hospital. The chief complaints were shortness of breath, cough, hemoptysis, dizziness and swelling of the legs. At the time of admission the clinical picture was that of a severe cardiac break, with failure of the right side of the heart and the usual signs and symptoms of visceral passive congestion. After the establishment of compensation he was discharged November 6, 1926. There were thirteen subsequent admissions with only slight variations in the clinical picture. On one admission the red

cell count was 6,000,000, on three admissions, 5,000,000 or above, on four, 4,500,000 or above, and on six admissions, between 4,000,000 and 4,500,000. While the red cell count did not invariably present a true polycythemia, in our experience with negro cardiac patients, a red cell count of 4,000,000 is above the average. The blood pressure varied between 170/135 and 110/85, a constant low pulse pressure and high diastolic pressure. On three admissions cyanosis was recorded as an objective sign. This is of particular significance because the patient was a negro and cyanosis can easily be overlooked in one of this race. Right sided heart failure was dominant in all fourteen admissions. The blood Wassermann reaction varied: on two admissions it was +++++, once, +++, once, +, and negative at other times. On the eleventh admission the Kahn reaction was ++. In the early course of his illness, over a period of eleven months, he received three injections of neoarsphenamine of 0.6 gm each, without evident improvement. The cardiac breaks occurred at shorter intervals during the course of observation, and the establishment of compensation became increasingly difficult, necessitating massive venesections

FIG 1 Longitudinal and cross section of a small pulmonary artery, the media is hypertrophied. There is a nodular thickening of the intima, almost occluding the lumen. $\times 250$

during the last three admissions. The patient succumbed March 11, 1931, approximately five years after the onset of symptoms. A necropsy was performed three hours after death.

Necropsy The body was that of a well nourished negro male of some 45 years of age, 172 cm in length, and of estimated weight of 95 kg. There was considerable edema so that the skin was tense. The superficial veins of the neck were distended. A slight excess of clear fluid was found in the peritoneal, and both pleural, cavities. A few fibrous adhesions bound the bases of the lungs to the parietal pleura. The lungs were heavy and soggy, and crepitant throughout. The cut surfaces were dark red, much fluid blood flowed from the cut vessels. There was 100 cc of clear fluid in the pericardial sac. The heart weighed 675 gms. All chambers were dilated and filled with blood, on the left side fluid, and on the right coagulated. The endocardium was smooth but in the left atrium and ventricle it was slightly thickened. Of the valves there was nothing noteworthy. The measurements in centimeters of the valve orifices were as follows: aortic, 7, pulmonary, 7.5, mitral, 12.5, and tricuspid, 15 cm. The wall of the left ventricle was

17 cm in thickness and of the right ventricle, 0.5 cm. A few yellow patches were seen in the intima of the aorta, increasing in number downward. The wall of the inferior vena cava was noticeably thickened. A few raised yellow patches were seen in the intima of the coronary arteries. There was passive congestion of the liver, spleen, kidneys, and intestines.

Microscopical sections revealed nothing noteworthy except in the lungs. The most striking change in the sections from the lungs was the prominence of the small arterioles. They were tortuous and the walls were thickened, the thickening being due to an increase in the width of the media. Both the muscle and the elastic tissue of the media were hypertrophied. The lumina were narrowed. In some of the smaller arteries and in the arterioles there was an increase in the thickness of the intima due to fibrosis. Occasionally the lumen of a small arteriole was almost obliterated by a proliferation of cellular connective tissue, in which were small endothelial lined spaces. Rarely thrombi were observed. The adventitia of the arteries and the veins was increased. A few small veins contained thrombi. There was an increase of the connective tissue of the walls

FIG 3 Cross section of a pulmonary arteriole. The lumen is obliterated by connective tissue which contains vascular spaces. $\times 500$

of most of the alveoli and sometimes the capillaries were obscured, the wall appearing as an avascular thin layer of hyaline connective tissue. The connective tissue about the bronchioles was increased, the lumina of the bronchioles narrowed, and the folds of the mucosa exaggerated. The muscularis of the bronchioles was hypertrophied. After prolonged search no *Spirochaeta pallida* were found in sections from the lungs.

COMMENT

From the history, clinical course and the pathology of this case the term primary sclerosis of the pulmonary artery is justifiably used. Such changes as were seen in the bronchi, lungs and

heart were secondary to the sclerosis of the arteries. On some occasions the Wassermann reaction was positive but no specific lesions were found at necropsy and, although the necropsy was performed soon after death, *Spirochaeta pallida* were not found in the lungs or in the lesions of the arteries of the lungs. There was no significant etiologic factor brought to light in the history.

Congenital hypertrophy of the media or faulty development may predispose the small pulmonary arteries to the obliterative changes that are observed in these cases.

Gonococcal Endocarditis*†

Summary of the Literature and Report of a Case

By ARTHUR M. HOEFMAN, M.D., and FLOYD C. TAGGART, M.D.,
Los Angeles, California

THAYER,¹ in 1922, stated that "gonorrheal cardiac infections as a whole are by no means very unusual" In contrast to the wide prevalence of gonorrheal urethritis this cardiac complication is rare Thayer, at that time, reviewed the literature and reported seventy-two cases including twelve new ones of his own In a comprehensive survey of the literature since 1922 we can find reported only eight authentic cases, to which we add another

CASE REPORT

A white woman, aged 19, maid, was admitted to the Santa Fe Coast Lines Hospital, Los Angeles, on July 13, 1930, as convalescent from an operation for acute appendicitis The operation had been performed at Phoenix, Arizona, on July 2, 1930 She had been seized with abdominal pain, nausea, and diarrhea on July 1, 1930 Her temperature previous to operation was 101.4° F, pulse 116, respirations 22 Leucocytes were 17,950, with polymorphonuclears 89 per cent Rigidity and pain were localized to the right lower quadrant Laparotomy was performed the next morning, and an enlarged, moderately distended, hyperemic appendix was removed The pelvis was examined at the request of the patient, and a retroverted uterus, but no other pathology, found The

post-operative course was stormy, with fever to 105.4° F A blood culture was taken at this time and was reported sterile On July 12th, ten days after operation, she was transported from Phoenix to Los Angeles

Physical examination, on admission to the hospital, revealed a small, fairly well developed young female, 5 feet 4 inches tall, weighing 110 pounds Scalp, no abnormalities Eyes pupils reacted to light and distance No jaundice, strabismus or nystagmus No exophthalmos or lid-lag Conjunctivae were of fair color and free from petechiae Fundi revealed no abnormalities Nose and Ears showed no abnormalities Mouth tongue dry and coated Tonsils hypertrophied Mucous membranes injected Herpes simplex limited to the left side Neck bilaterally enlarged cervical glands No venous fillings or pulsations Thyroid not enlarged Lungs equal movement, normal resonance Breath sounds vesicular No râles Heart no demonstrable hypertrophy to percussion Rate 106, regular, P₂ greater than A₂ Blood pressure 110/70 Abdomen draining operative wound in right lower quadrant Liver and spleen not palpable No masses Extremities no clubbing, tremors or deformities There was marked hyperextension of the elbows Reflexes knee jerks, ankle jerks, biceps, triceps and abdominals, present, equal, and active Skin normal texture, somewhat pale Pelvic examination not done Urine cloudy, specific gravity 1024, acid, sugar absent, albumin trace, acetone absent, moderate number of pus cells, a few epithelial cells, no casts Blood hemoglobin 67 (Sahli), red blood cells 4,200,000, white cells 13,200, with 81

*From the Santa Fe Coast Line Hospital, Los Angeles, California

†Received for publication, August 10, 1931

per cent polymorphonuclear neutrophils, 8 per cent lymphocytes, 11 per cent large mononuclears Wassermann test negative

The temperature of 100° F on admission ranged from 98.4° to 100° F during the first ten days Drainage from the abdominal wound persisted At times, a scanty vaginal discharge was noted, and a cervical smear contained a moderate number of gram-negative intracellular diplococci, morphologically gonococci The patient developed bilateral lower abdominal pain and it was thought that a salpingitis might be present Hot vaginal douches gave relief

July 23 hemoglobin had dropped to 58 (Sahli), red count 4,020,000, white count 9,200, with 81 per cent polymorphonuclear neutrophils Temperature is recorded in chart reproduced as figure 1

A blood culture taken July 30, and planted on Swartz agar plus one-third hydrocele fluid, remained sterile Smear for malaria was negative Quinine sulphate had no effect on the fever

By August 3 the abdominal wound had stopped draining and was closing

August 5 hemoglobin was 48 (Sahli), red blood count, 3,510,000, white blood

count, 9,800 with 75.5 per cent polymorphonuclear neutrophils The red cells showed a slight degree of achromia

August 8 400 c.c. of whole blood was given

August 10 the genito-urinary consultant stated, "Purulent discharge from urethra Moderate cervical discharge Bartholin glands not involved Neither tube palpable No evidence of abscess Complains of some frequency and burning This is due to the urethritis Advise no local treatment until she is able to be up"

August 15 hemoglobin was 51 (Sahli), red blood count, 3,610,000, and the white blood count, 14,300, with 82 per cent polymorphonuclear neutrophils

August 26 patient was seen by one of us and the following note made "After period of fever for thirty-two days post-operative with leucocytosis, negative blood culture, no definite petechiae, clubbing, heart murmur or palpable spleen, temperature subsided for three or four days, then recurred There is a progressive secondary anemia The spleen is now definitely palpable A loud blowing systolic murmur can be heard at the apex whether due to anemia or endo-

FIG 1

carditis cannot be stated. There are no visible petechiae but there is suggestive clubbing of fingers. Blood culture to be repeated for gonococci. Hemoglobin, on this date, 38 (Sahli), red blood count, 3,000,000, white blood count, 7,400, with 87.5 per cent polymorphonuclear neutrophils.

September 3 three petechial spots found on the left hand.

September 5 hemoglobin, 33 (Sahli), blood count, 2,480,000, white blood count, 5,100, with 83 per cent polymorphonuclear neutrophils.

September 6 transfusion of 350 c.c. whole blood.

September 9 laboratory reported as follows: "Blood cultures on Swartz agar plates with hydrocele fluid were sterile after seven days. Glucose broth with an equal amount of hydrocele fluid incubated four days and transplanted to Swartz hydrocele slant showed positive culture in 24 hours. Organisms were gram-negative, biscuit-shaped diplococci in pure culture. Culture positive for gonococci."

September 9 progress note by one of us: "Blood culture for gonococci finally positive on second culture. Change in heart murmur. Definite diastolic blow localized to third and fourth interspaces to left of sternum." Electrocardiogram showed sinus tachycardia. Rate 100, with upright P, T and QRS complexes in all leads. Patient was too ill to do an orthodiagram.

September 12 hemoglobin, 29 (Sahli), red blood count, 1,980,000.

September 13 transfusion 500 c.c. whole blood.

September 15 hemoglobin, 32 (Sahli), red blood cell count 2,060,000.

September 17 acriflavin hydrochloride, 0.3 gm, given intravenously. A transfusion of 500 c.c. of whole blood from a patient convalescent from gonorrheal arthritis was administered. On this date, a third blood culture was taken and was reported positive for gonococci, thus making the second positive culture.

September 19 hemoglobin, 38 (Sahli), 2,180,000, white blood count, 6,400, 83 per cent polymorphonuclear neutrophils.

September 21 acriflavin hydrochloride 0.45 gm intravenously.

September 24 "Sudden hemoptysis to-

day. Probable pulmonary infarct. Several new petechiae on anterior chest wall. One in right lower lid has disappeared."

September 26 "Condition grave. Innumerable petechiae. Marked clubbing of fingers present."

September 29 patient died.

Autopsy performed by Coroner's Surgeon John H. Schafer, September 30, 1930, was reported as follows:

"I performed an autopsy on September 30, 1930, at the Los Angeles County Coroner's Mortuary, and found the body jaundiced, graded three. There were many petechiae in the skin over almost the entire body.

"Upon opening the body, the heart was found to be about normal in size and there was a purulent pericarditis. Smears from the pericardial exudate revealed no organisms. The epicardium showed numerous petechiae and there were a few petechiae in the myocardium. The leaflets of the mitral valve were the site of large vegetations (see figure 2) and smears from these revealed large numbers of gram-negative, intracellular diplococci morphologically identical with the gonococcus. No other gross lesions of the heart were found.

"Both lungs showed an extreme degree of congestion and edema with innumerable small hemorrhagic foci, with many small pin-point abscesses in the center of the hemorrhagic foci. The hilus of the right lung showed what appeared to be a beginning infection by direct extension from the adjacent pericardium.

"The spleen weighed 800 grams, was very soft and showed many large infarcts.

"The kidneys were about normal in size and the right one showed a number of small septic infarcts.

"The liver was jaundiced, pale, and there was a fibrinopurulent deposit on the right dome.

"The intestines in the lower portion of the abdomen were covered with a light fibrinopurulent exudate and were lightly adherent. The appendix was missing. The uterus and adnexa were covered with a similar exudate and were lightly adherent to the surrounding structures. The tubes and ovaries showed no gross lesions except the exudate described. The uterus was very small, sharply anteflexed, and the cervical canal

showed the typical palmate folds of the virgin uterus. The uterus had not been pregnant. There is a history of recent positive smears for gonococci from the cervix."

Since Thayer's review of the subject of gonorrheal endocarditis in 1922, there have been in all nineteen case reports of so-called endocarditis with gonococci as the etiological agent. We say "so-called" because of the lack of absolute evidence culturally in most of these case reports. Thayer admits the necessity of positive blood culture intra-vitam, or post-mortem culture from the heart valve, for diagnosis. In the twenty cases which he reports from the Johns Hopkins Hospital records, fourteen were so proved. Six had negative blood cultures intra-vitam and only bacterioscopic evidence

of gonococci on the heart valves post-mortem. All of these cases, however, had either a specific urethritis or positive smears from the cervix uteri. They, therefore, are presumptive cases, only, probably satisfactory clinically but not bacteriologically.

We hold with Karsner² that "gonococcal endocarditis must show the presence of gonococci in the blood or lesion to be accepted as such." We would further add that the determination of gonococci from the lesion, post-mortem, is certain only by culture. Either positive intra-vitam culture or post-mortem culture from the lesion is essential to an absolute etiological diagnosis. Smears from the heart lesions without culture and with

FIG 2

negative blood culture intra-vitam would be presumptive evidence only

In dealing with gram-negative diplococci, the difficulty of differentiation between gonococci and meningococci must be considered. Only within recent years have the cultural differences between these two organisms been made with any degree of certainty. This differentiation is particularly important in view of the numerous recent case reports of meningococcus septicemia with or without endocarditis, most of the cases without meningitis. On clinical grounds there seems little possibility of confusing these two types of septicemia. As stated above, Thayer's negative blood and valve culture cases all had specific urethritis or cervicitis as a point of differential diagnostic value clinically. The not infrequent association, however, of positive gonococcic urethritis or cervicitis and an endocarditis due to a secondary invading organism, as the streptococcus, staphylococcus, or pneumococcus, must be kept in mind. It is in cases of this type, with negative intra-vitam blood cultures, that the possibility of error in considering them instances of gonorrheal endocarditis arises.

Cases reported by Aubertin and Gambillard,³ Villela and Torres,⁴ Bard, Langernon and Gardère,⁵ Gallois,⁶ Edwards,⁷ Johnston and Johnston,⁸ Kramer and Smith,⁹ McCants,¹⁰ Klein,¹¹ Lion and Levy-Bruhl,¹² and Herzog and Kouzmin,¹³ all lack positive blood cultures intra-vitam or positive cultures from the post-mortem lesions. Most of them can be classed as clinically presumptive but unproved cases.

Authentic culturally proved cases

have been reported since 1922 by Gallois,⁶ Barbe and Meynet,¹⁴ Riecker,¹⁵ Brebner,¹⁶ Pratsicas,¹⁷ Vander Veer,¹⁸ Kramer and Smith,⁹ and Perry.¹⁹ These eight with our one case make only nine authentic cases since Thayer summarized the literature in 1922. The seventy-two cases which he reviewed included at least six which were presumptive only, making a total to date of only seventy-five culturally proved cases. This small number is in striking contrast to the wide prevalence of gonococcus infection. Of Thayer's reported group only five cases recovered. Since his report only one instance of recovery can be found. Repeated small transfusions seemed to be the factor of importance in the recovery in this instance. In our patient, similar transfusions were of no avail. Tabbutt²⁰ reported two instances of gonococcus septicemia with positive intra-vitam blood cultures without endocarditis, both proved at autopsy. Such findings emphasize the importance of autopsy confirmation of the presence or absence of endocarditis in the presence of culturally proved septicemia.

The value of complement fixation as a diagnostic aid in gonococcus endocarditis is questionable. Because it raises this question and also because of the relative inaccessibility of the article, we summarize the case report of Herzog and Kouzmin,¹³ of Moscow.

An adult male developed an acute urethritis on November 1, 1926. Under local treatment the discharge subsided but the patient persisted in running a temperature from 37° to 40° C for almost three months. On December 29 a blood culture was sterile. A systolic murmur developed. He suffer-

ed pain in the left kidney region, interpreted as due to an embolus. Complement fixation reaction was positive. Autopsy on February 9, 1927, demonstrated a vegetation on the mitral valve. Smears or cultures are not reported. They base their diagnosis of a gonococcic endocarditis on the presence of the urethritis, continued fever, systolic murmur, vegetation on the mitral valve, and a positive complement fixation test. In what manner the complement fixation reaction can be considered specific for gonorrheal endocarditis we do not know. It seems reasonable to presume that gonococcic urethritis alone would make it positive, and so include this case report, as one of the presumptive clinically but unproved culturally cases of gonococcal endocarditis.

SUMMARY

1 The literature on gonococcus endocarditis is summarized to date.

The eight authentic cases reported since 1922 are reviewed. To these we add another. They make a total of seventy-five proved cases of gonococcus endocarditis in the literature.

2 The criteria of diagnosis are discussed. A positive diagnosis of gonococcal endocarditis can be made in the presence of clinical evidence of endocarditis only when intra-vitam blood cultures are positive for gonococcic or when cultures from post-mortem lesions reveal the same organism.

Since the writing of this article an additional authentic case of gonococcal endocarditis, proved by postmortem culture, has been reported by H. B. Kirkland.²¹

The Value of Knowledge of Personality

“FORECASTING the future of body-minded man, and not a decapitated being, is an interesting and, on certain occasions, a wise precautionary measure. We should not, however, allow our forecasting proclivities to divert attention, as so frequently happens today, from the importance of acquainting ourselves with the knowledge that can be readily obtained from reviewing the data supplied by heredity, environment, physical characteristics, the nature of the emotional and mental reactions, the habits of life, the tendencies to face or dodge reality, academic tests, estimates of intelligence, and information bearing on the social environment and the reactions of the individual to the people with whom he is brought into contact. Without this information we can only try in a very bungling manner to direct the expenditure of human energy. Unless we have definite information in regard to the individual personality, we can only expect to make ridiculous attempts to fit young people for school, college, business, industry or life. Without this information we should not expect to be much more successful than we are at present in fitting children into home surroundings, struggling students into academic environments, apprentices into their trades, business men into bigger business enterprises, and misfits of various kinds into society.

(From *Prohibiting Minds and the Present Social and Economic Crisis*, by STEWART PATON, M D, Paul B Hoeber, Inc, New York City)

The Significance of Lymphatic Tissue and Adenoma-Like Areas in the Thyroid Gland* ** †

By L. R. HIMMELBERGER, Ph D, *Flint, Michigan*

WHILE the terms Graves' disease, Basedow's disease and exophthalmic goiter are purely clinical expressions and their use in pathological connections perhaps questionable, no suitable pathological term exists that is descriptive of the changes seen in the thyroid gland in this disease. Parenchymatous hypertrophy and hyperplasia have been used quite properly but these expressions do not describe the most important changes seen, as we hope to show. The present clinical tendency to consider "toxic adenoma" as a condition separate from Graves' or Basedow's disease also lends confusion to a pathological understanding of the process in the thyroid gland.

The association of thyroid disease with a general lymphadenopathy and the idea that in some way or other it was related to changes in the thymus is by no means a recent conception, for as early as 1905 Hansemann¹ reported four cases of Basedow's disease coming to necropsy in which a general lymphatic hyperplasia was observed.

*From the Laboratory of Hurley Hospital, Flint, Michigan

**Thesis presented to the Faculty of Michigan State College, in partial fulfillment of the requirements for the degree of Doctor of Philosophy

†Received for publication, April 15, 1931

At that time he suggested a relationship between thyroid and "status lymphaticus". In 1908 Capelle² also took a similar attitude and in 1911, with Bayer,³ reported beneficial results from thymectomies on Basedow patients. Bircher,⁴ in 1912, reported experiments in which he produced Basedowian symptoms in dogs by implantations of thymus glands from patients suffering from thyroid disease. Pettavel⁵ wrote on the pathological anatomy of Basedow's disease in four well studied cases. In two cases he found a persistent thymus, in all he found areas of lymphoid tissue in the thyroid gland, and in three there existed a general hyperplasia of the lymphatic tissue throughout the body. He failed, however, to place diagnostic significance on the lymphoid hyperplasia in the thyroid. Matti⁶ reported necropsies on ten cases in which general lymphoid hyperplasia was a striking feature. In but one case did he fail to find lymphoid follicles in the thyroid. This patient was a twelve year old child however, and one may properly question the existence of Graves' disease. Rautmann,⁷ also studying the pathological anatomy, demonstrated a general lymphadenopathy with lymphocytic infiltration in the thyroid. Pettavel⁸ reported addi-

nional work in 1914, and Klose,⁹ in 1916, also called attention to the general lymphoid hyperplasia existing in thyroid disease

In this country many writers have mentioned the presence of pseudo-nodes, lymphatic tissue, round cell infiltration, etc, in the thyroid gland McCallum's¹⁰ is the only text book on General Pathology which refers to these areas He says that definite lymphoid nodules are found in exophthalmic goiter and but rarely if ever found in normal glands He fails however to ascribe any significance to their presence Aschoff,¹¹ while lecturing in this country, spoke of the presence of pseudo-nodes in both Basedowian and non-Basedowian glands, and observed that they are more frequently found in glands from Basedow patients Sager¹² mentioned the presence of lymphocytes, but evidently did not consider them of significance Rienhoff¹³ gave them a place in the pathological picture of thyroid disease, but evidently did not consider them to be of diagnostic importance Broders¹⁴ has always considered them to be evidence of thyroiditis Menne, Joyce and Von Hungen¹ also believed them to be of inflammatory origin Warthin¹⁵ was the first in this country to point out the pathological significance of areas of lymphatic hyperplasia He alone at that time (1924) considered rudimentary lymphoid areas as being of diagnostic importance, thus definitely suggesting a new diagnostic criterion in Graves' disease, the essential pathological changes of which have been considered, for nearly 40 years, to rest exclusively in the acinar epithelium

and amount of contained colloid It was Warthin's observations that first engaged the writer's interest and stimulated the study in this laboratory Elovzin¹⁷ working here in 1927 made a limited study of our material then available It was Warthin's contention in 1924 and again in 1929 that the presence of lymph tissue was diagnostic of potential Graves' disease or exophthalmic goiter He gave further impetus to the idea held by the previously quoted continental observers that this tissue indicates a definite pathological constitution, the so-called thymico-lymphatic type of individual, or as he preferred to call it, the "Graves' constitution" He pointed out that these individuals present a hyperplasia of the lymphoid tissue throughout the body and took the position that they have a congenital predisposition to Graves' disease In a recent survey of one hundred and eighty-one post-operative cases, Clarke and Black¹⁸ also concluded that a constitutional factor is involved Simpson¹⁹ supports this view in a study of 665 resected thyroids On the other hand, Hellwig²⁰ in a recent article opposed Warthin's views, basing his conclusions on a study of fifty-eight surgical and seven postmortem specimens He concluded that the presence of lymphocytes in the thyroid is the result of a simple local reaction to hyperactivity of the gland, that they are of no diagnostic importance and can in no way be interpreted as evidence of a so-called Graves' constitution Sixty-six per cent of his cases presented lymphocytic infiltration and he cites a group of cases without clinical symptoms in which these areas were present in

38.5 per cent. He does not state the reasons or indications for the surgery in this latter group. One is led to believe that he assumes lymphocytic infiltration to be present in 38.5 per cent of normal glands.

It is the purpose of this paper to present an interpretation of the significance of lymphatic tissue in the thyroid gland as gained from a study of material collected over a period of six years, consisting of (1) thyroids from stillborn infants, premature births, and very young children coming to necropsy, (2) surgically resected thyroid glands and, (3) necropsy material from older subjects who died from conditions not in any way involving the thyroid gland, together with observations on the so-called adenomata of the thyroid.

If Warthin's thesis is tenable, that there exists a definite type of individual possessing a "Graves' constitution," who is potentially a case of exophthalmic goiter, that constitution must be congenital and the significant lymphatic areas should be present at birth or even in uterine life. A routine search of thyroids of young subjects should, therefore, be rewarded with a certain percentage incidence of the lesion. Material for this section of the study consists of thyroids from 140 full term, premature and still-born infants. Further, if the lesion under consideration is a part of the "Graves' constitution", and is of diagnostic significance, it should be present in all cases of true Graves' disease and it should be capable of demonstration in practically all resected glands from such cases. This material consists of three hundred and eighty-six glands

removed surgically. Still another point of proof susceptible to demonstration rests in a study of supposedly normal glands obtained at necropsy.

According to Warthin's thesis not all of those individuals possessing this "Graves' constitution" develop clinical Graves' disease. It should, therefore, be possible to show a small incidence of the lesion in question in postmortem material from subjects devoid of thyroid history. While this incidence should be less, it should be roughly comparable with that found to be existent in the glands of infants, prematures, etc. Our material studied in this connection consists of glands from two hundred cases selected from the standpoint of a nonthyroid history.

The normal thyroid has been quite intensively studied by many workers. No attempt will be made here to present a review of this literature. Suffice it to say, that in all the literature consulted, no mention is made of the presence of lymphatic tissue in the normal thyroid except by Marine,²¹ who said merely that lymphocytes do occur normally. He dismissed the subject with a single sentence and failed to state the extent to which it was observed.

Williamson and Pearce²² in an extensive study of the normal gland made no mention of lymphoid tissue. Rienhof,²³ working with serial sections and using reconstruction methods, said nothing of their presence in normal glands. In view of the fact that lymphoid areas failed to attract the attention of most investigators of the normal gland, one may feel safe in assuming that such tissue is not a com-

mon histological component of the normal thyroid

STUDY OF INFANT THYROIDS

This material, as before stated, was secured from premature fetuses, still-born infants, and infants that lived but a short time after birth. Most of the material came from still-born infants, but we have several specimens from fetuses as young as the fifth month of gestation. In passing, it is perhaps of interest to note that colloid was present in the acini of these fetal thyroids to a greater or less degree. This is in keeping with the observation of Murray¹ and others quoted by him. A search of the literature reveals few studies of fetal or infant glands, Murray makes no mention of lymphocytes, neither does he speak of adenomata. Rautmann, however, did observe small areas of lymphocytes in rare instances while studying glands from very young children. Warthin also mentioned their occurrence in rare instances. Our study of glands from these cases was confined to a search of microscopic preparations for areas of lymphocytes and to observations on the presence of adenomatous areas.

The histological picture of the thyroid gland from the young subject is quite constant. Maturity of the epithelial cells lining the acini is apparently established prior to birth and colloid storage is a pre-natal function of the gland, at least as early as the fifth month. Murray has shown that post-mortem desquamation of acinar epithelium is responsible for the appearance of acini filled with epithelial cells. This is also our experience. Study of microscopical sections from one hundred and forty glands from

the sources above outlined revealed the presence of lymphoid areas in four cases only. Two of these were still-born infants, one was a baby three weeks old, dying from hemorrhagic disease of the new-born, while the other was an infant that lived for but a few hours after birth, death being due to cerebral hemorrhage. These results give a percentage incidence of the lesion of approximately 2.8 per cent. Had more material been available a more accurate incidence would of course have been established, as it is very obvious that in a matter involving low percentages a large mass of material is quite essential. These results, however are indicative of findings that could confidently be expected in a large number of cases. A further consideration of this percentage incidence will be taken up in connection with postmortem material from older subjects. There was one case in which the lymphoid bodies were found which was not included in the series because of the other pathology present. This was a case of a child nine months old, dying a so-called thymic death. This case was previously reported by the writer²⁵ and the observation made at that time was that no areas of rudimentary lymphoid tissue were found in the thyroid parenchyma. During the progress of this work a re-study of this case was made, new sections were cut and an intensive search revealed the presence of lymphoid areas. This experience points out the necessity of numerous blocks and careful search.

Of the one hundred and forty specimens examined, areas of so-called "fetal" adenoma were observed in three cases. These areas are separ-

ated from the adjacent parenchyma by a thin fibrous connective tissue capsule and there is a definite difference in the appearance of the cellular structure. Little or no colloid is seen in these areas, the cells are very compact, and take a much deeper nuclear stain.

RESECTED THYROID GLANDS

In a study of surgical material, the conclusions at which one may arrive are made difficult by the perplexing question of the clinical diagnosis as recorded on the patient's chart and because of the paucity of the clinical information, for it is upon these clinical records that the comparative study must be based. With the aid of experienced clinicians we have attempted to classify our material into two groups (1) those cases showing undoubted clinical evidence of Graves' disease and (2) those cases in which the data in the record did not warrant such a conclusion, or cases which were definitely diagnosed as not of a Graves' character. The criteria used for the first group were Tachycardia, exophthalmos, tremor, increased pulse pressure, definite loss of weight and increased basal metabolic rate. Cases showing any three of the above clinical symptoms were considered, perhaps liberally, as true Graves' disease. All others were placed in the second group. It is very obvious that errors in classification are certain to occur inasmuch as the information in some instances was meagre and incomplete, not representing, perhaps, a true picture of all the clinical signs present.

Slides from 386 surgical cases were studied with the following histological findings

Lymphatic tissue with no epithelial hypertrophy	123
Hypertrophy of epithelium with lymphatic tissue	62
Hypertrophy of epithelium with no lymphatic tissue	4
Hypertrophy, lymphatic tissue and adenoma	12
Lymphatic tissue and adenoma	59
Adenoma, iodization and degeneration	7
Colloid gland only	45
Cystic degeneration without hypertrophy or lymphatic tissue	28
Iodism	46
	<hr/> 386

Examination of the tabulated observations, shows the presence of lymphoid tissue in 246 cases, while epithelial hypertrophy existed in but 68 cases. There were four cases showing epithelial hypertrophy without lymphatic areas. These cases were among our earliest material and but few blocks were available in each case. We feel that had sufficient material been available the lesion could have been demonstrated in these cases. The low incidence of epithelial hypertrophy is in striking contrast to the high incidence of lymphoid areas and represents a valuable feature in the study of these glands. Were epithelial hypertrophy the only pathological change considered as indicative of Graves' disease, a marked difference between clinical and pathological findings would exist, since of the 246 cases showing rudimentary lymphoid tissue, all but eleven had been diagnosed, or showed definite clinical signs of, Graves' disease, as did the four cases showing epithelial hypertrophy only. The eleven cases not classified as clin-

ical Graves' disease were cases with a very meagre history in each instance, with the clinical diagnosis given as "toxic goiter", which would perhaps warrant their classification as Graves' disease since, clinically, this term is often used interchangeably with Graves' disease. Of the other 140 cases, nine had been classified according to our standards as clinical Graves' disease. The fact that these failed to show lesions of the disease is, we feel, due to our liberal clinical requirements or to having "missed" the areas because of an insufficient number of blocks having been taken. Two of these cases were classed pathologically as undergoing degeneration, four as iodism, while in three no definite changes could be detected. The data presented emphasizes the importance of recognizing the presence of lymphoid tissue and its interpretation as a pathological feature of Graves' disease, since practically all cases showing the classical clinical signs of the Graves' syndrome present the lesion in question.

Those glands classified as adenomatous all contained encapsulated areas of atypical thyroid tissue in different stages of development, but no case showing adenomata as the only deviation from normal presented true clinical signs of Graves' disease. The clinical adenoma described by clinicians is not, in our opinion, an adenomatous structure at all but merely represents a nodular portion of the thyroid containing perhaps large amounts of hypertrophic tissue. We have observed in a few cases that the areas of lymphoid tissue are more numerous in these nodular structures than in tissue taken at some distance from the

nodular portions. We feel that this accounts for the so-called "toxic adenoma" and the prevailing impression that removal of the "adenoma" gives clinically beneficial results. That there is some doubt as to the permanency of these beneficial results is shown by the recent survey of Clarke and Black.¹⁸

There were twenty-eight cases of large glands showing no evidence of Graves' disease. These all showed, grossly, areas of degeneration of various degrees, some adenomatous, but consisting for the most part of colloid cysts containing old hemorrhage and softened tissue. A few were undergoing calcareous degeneration and an occasional one showed definite necrosis. It is possible that tissue dissolution products in these degenerated glands may supply a toxic amount of the thyroid hormone and thereby cause symptoms that clinically simulate the Graves' syndrome, thus being responsible for many diagnostic errors. This point seems susceptible to experimental study and experiments embracing it are now in progress.

The forty-six cases reported as iodism demand consideration since the question of iodine-Basedow which formerly occupied a large place in the literature is now receiving but scant attention. According to Crotti,²⁰ individual sensitivity to iodine varies widely. Many patients tolerate large amounts of iodine, while in others, very small amounts are responsible for marked disturbances. Moreover, some of those who have previously shown good tolerance to iodine preparations suddenly develop pronounced symptoms of iodine-Basedow. In this day of iodine salt (particularly in

Michigan) and proprietary reducing nostrums containing iodine, when practically everyone is receiving iodine constantly or at intervals, it seems to us that the question is deserving of more consideration than ever. Warthin contended that over-iodization will produce clinical signs simulating Graves' disease. Jackson²⁷ also writes of a type of hyperthyroidism being caused by iodine. In one of our cases diagnosed clinically as Graves' disease by the physician, and having a basal rate of $+30$, together with a mild tachycardia and slight loss of weight, we failed to find lymphoid areas. Upon investigation it was found that this patient had previously been using proprietary goiter remedies containing iodine, and had been further iodized by his physician. Histologically, the tissue presented all of the involutional changes described as due to iodination.

Warthin reported in 1924 an analysis of 976 resected glands. Of these, 247 presented areas of lymphatic tissue while 154 showed both lymphatic tissue and epithelial hypertrophy. A large portion of Warthin's material was collected before the extensive use of iodine as a preoperative therapeutic procedure which no doubt accounts for the greater incidence of hypertrophic epithelium as compared to our results in this connection. The remainder of the cases studied by Warthin showed no evidence of Graves' disease and the physical findings did not warrant such a diagnosis.

The absence of epithelial hypertrophy in a large proportion of the specimens is no doubt due to epithelial involution due to iodine therapy. Many observers including Sager, Rienhoff

and Warthin have pointed out the involutional effects of iodine in exophthalmic goiter. At the present time practically all cases of Graves' disease coming to surgery are iodized preoperatively, consequently a non-treated surgical specimen is rare indeed. Rienhoff, in particular, studied the effect of iodine on the involution of thyroid epithelium in exophthalmic goiter. His observations were made upon seven well considered cases in which artificial involution was studied at various stages. He describes the changes due to iodine as follows:

- "(a) Increased amount and density of colloid
- (b) Increase in size and regularity of acini
- (c) Increase in amount of connective tissue in the septum and scarring throughout the gland
- (d) Decrease in size and height and change in shape of epithelial cells from a high columnar to a cuboidal or endothelial cell
- (e) Decrease in cytoplasmic bodies or constituents
- (f) Decrease in vascularity of gland
- (g) Decrease in vacuolization of colloid and deposits of lymphocytes"

Warthin believed that overiodination produces a "watery" colloid and that lymphocytic exhaustion of the germ centers of the lymphoid tissue results. In our experience extensive iodination also causes marked atrophy of the epithelial cells lining the acini, the cytoplasm is decreased and the nucleus contracted and deformed. We have been unable to show a definite difference in the lymphoid areas in overiodized and underiodized specimens because of our inability to surmount the difficulty of obtaining specimens from the same patient before and after iodination.

SELECTED POSTMORTEM THYROIDS

In a study of the thyroids from 1000 autopsies Warthin found 32 showing areas of lymphoid tissue. Two of these were also carcinomatous. These findings give a 3.2 per cent incidence of lymphoid areas in a routine examination of all cases coming to necropsy. These cases were evidently not selected with reference to the exclusion of thyroid involvement and possibly included some cases which had previously suffered from Graves' disease.

As before stated we studied slides from 200 cases without thyroid involvement, many of them in the younger age groups (early part of first decade). In this study we made the following observations:

Epithelial hypertrophy	0
Lymphatic tissue	4
Areas of adenomatosis	9

The percentage incidence of lymph tissue was 2 per cent. While this is considerably lower than Warthin's figures it corresponds to the incidence of these areas found in infant glands, since theoretically the incidence should be higher in the case of the latter. It will be seen that the incidence of adenoma-like areas in selected necropsy and infant material is also within comparable limits.

ADENOMA

A study of this surgical material has made possible observations regarding adenoma. Many clinicians consider toxic adenoma a disease independent of Graves' disease, but as before stated, the clinical term "adenoma" has no reference to histology and is applied to nodular forms of thyroids which may not be involved in Graves' disease. Reinhoff from his series of seven care-

fully studied cases of exophthalmic goiter in which involution was established by the administration of iodine, came to the conclusion that a large proportion of those areas considered adenomata are but residual areas of hypertrophy and hyperplasia which have remained refractive to iodine or because of disturbed vascular supply have not been subjected to its influence. Ewing's miliary adenomata were considered by him to be such areas. He offered as a possible explanation for the failure to secure permanent remission from iodine the suggestion that these areas of persistent hypertrophy maintain a state of hyperthyroidism. Warthin considered the adenoma of the thyroid as a congenital anomaly due to altered vascular supply and therefore altered development results. Ewing considered the fetal adenoma as being embryonal. Menne, *et al*, considered adenoma as a separate division in their system of classification.

Our observations have disclosed the following facts:

1 Small areas of adenoma-like structures are capable of demonstration in certain slides from infant thyroids. These areas present a cell arrangement distinct from the balance of the tissue.

2 Adenomatous areas, both the so-called "fetal" and mature types, are seen in postmortem material from selected non-thyroid cases.

3 These adenomatous structures are quite as frequently found in non-toxic glands as in so-called toxic cases. Figure 1 shows a gross specimen of adenoma and figure 2 shows an area of lymphocytes in the thyroid tissue outside the encapsulated area at "A".

4 A study of 100 glands from

FIG 1 Gross specimen of thyroid with adenoma, to show area from which figure 2 was made

FIG 2 Photomicrograph showing an area of lymphocytes in the non-adenomatous tissue at 'A' in figure 1

dogs of all ages and breeds shows the presence of these adenomata in a small percentage of the glands

In view of the foregoing it appears to us that "fetal adenoma" bears no relation to thyroid disease. We have no cases of adenoma in our material which presented clinical signs of toxicity that were not shown to be Graves' disease, as determined by the presence of lymphoid tissue. The presence of these areas of adenoma-like structure in infant glands would tend to refute the conclusions of Rienhoff that they are persistent hypertrophic areas. Their presence in postmortem material of all ages, as well as in infants lends support to the view of Warthin that they are congenital structures. Their presence in dog thyroids leads to a safe assumption that they are in no way related to Graves' disease, *per se*, as dogs are supposedly not subject to the Graves' syndrome.

COMMENT

In this study of the occurrence of rudimentary lymphoid tissue and exophthalmic goiter we have included limited observations on the significance of adenomatous areas. The data presented from the examination of infant and selected necropsy material may be taken together when considering Warthin's hypothesis that these pseudonodules are evidence of constitutional deviations from normal. The presence of areas of lymphatic tissue in infant glands is perhaps of greater significance than their presence in the glands from necropsies of older subjects, inasmuch as one is not confronted by the question of pre-existing Graves' disease, although we have tried to obviate this factor in the selection of

our necropsy cases. We were unable to follow Warthin's study with reference to a general lymphoid involvement in exophthalmic goiter for the reason that but one necropsy case of exophthalmic goiter was available. In this one case, a female 50 years of age, cervical and mediastinal lymph nodes were enlarged and hyperplastic, the thymus was mildly persistent having a weight of 6 grams and the liver showed marked degenerative change. Menne *et al* take the position that lymphocytes in the thyroid gland are the result of inflammatory absorption reactions following sustained hyperactivity of the gland and that the "prolonged activity probably leads to the necessity for more supportive stroma." While there might be some defense for this reasoning regarding the presence of this lesion in adult thyroids, it is hardly conceivable that this explanation would hold in cases of infant glands. Furthermore, a considerable number of our specimens came from children succumbing to so-called "summer diarrhea" and it is interesting to note that none of these showed the presence of these areas. It would be a conceivable possibility that were they the result of a true inflammatory process, one would be able to demonstrate their presence in an infectious disease of this type in which there is a marked disturbance of all metabolism, and in which a general lymphadenosis exists. Numerous other childhood diseases were represented in our material and in no case were these areas of lymphoid tissue noted. In a case of miliary tuberculosis in a child 8 months of age, diligent search of many sections failed to disclose the presence of lymphoid areas in the face of the presence of a distinctly local

infectious process of acknowledged chronic type

Another case in point is our failure to find these areas after exhaustive search of many sections in a necropsy case of generalized tuberculosis in an adult even though a definite tuberculous process was demonstrated in the thyroid. Hellwig also believes that lymphocytic infiltration is the result of a purely local response, inflammatory in nature, but the number of his cases is small and he offers no assurance of exhaustive search for areas of lymphoid tissue. We have repeatedly called attention to the necessity of many blocks and intense study. We feel that the discrepancies occurring in our work are largely due to this factor. Figure 3 shows a small area of lymphoid tissue in a gland with extensive epithelial hypertrophy in all sections. This was the only area of lymphatic

tissue found, however, in sections from many blocks. Furthermore, it is not our experience that with these areas epithelial hypertrophy always co-exists. We have seen many cases in which no epithelial hypertrophy and but an occasional area of lymphoid tissue could be demonstrated in sections from many blocks. In one instance only a single area of lymphoid tissue was found in sections from nine different blocks, none of which showed hypertrophy of the epithelium. We fully agree with Warthin that epithelial hypertrophy persists longer in and about the lymphoid tissue in the face of iodination and feel that this is the proper interpretation when the two processes are found to be co-existent. These observations, in our opinion, indicate that the production of rudimentary lymph nodes does not form a part of the picture in inflammatory processes in

FIG 3 Photomicrograph showing the only area of lymphoid tissue found in numerous sections from a gland showing extensive epithelial hypertrophy

the thyroid gland and that the lesion in question is not of inflammatory origin

The almost universal presence of this lesion in surgical thyroids from patients exhibiting clinical Graves' disease is the main point of interest in the entire work, since Warthin's interpretation of lymphocytic areas as a diagnostic criterion is strongly supported. To us, there is a difference in the amount of lymphatic tissue and the degree of its hyperplasia, depending on the severity of the toxic symptoms of the patient and the degree of clinical response to iodine treatment. Figure 4 is a photomicrograph of a specimen from a patient whose basal metabolic rate, before iodine treatment was $+43$, improvement under iodine was very slight, the basal rate remained high and partial resection of the gland was of but slight clinical benefit. Later

a nearly total extirpation was considered necessary. The microscopical picture of the two specimens of thyroid gland were essentially identical, though nearly two months elapsed between the two resections. Lymphatic nodules were numerous throughout all sections and epithelial hypertrophy is persistent, particularly adjacent to the lymphatic tissue. On the other hand figure 5 is from a case with a few symptoms, basal rate of $+21$, and showing microscopically but an occasional area of lymphatic tissue, though many blocks were examined. While we have several such comparative instances we realize that definite conclusions would necessitate a painstaking study of a great number of cases with carefully taken histories. We have also observed that in those cases of infant and selected necropsy glands showing lymphatic tissue, definite

FIG 4 The marked development of lymphoid tissue in the thyroid of a severe case of exophthalmic goiter

hyperplasia is lacking, the tissue not showing very distinct germ centers (Figure 6) Continuing this line of reasoning it would follow that symptoms of Graves' disease manifest themselves only when these congenital areas become hyperplastic and further, that the more extensive the hyperplasia the more severe are the symptoms As said before it is our observation, as well as Sager's, that these areas persist in the face of evident adequate iodine therapy We do not know, however, that they are not reduced in number, size and degree of hyperplasia Rein-hoff, who has studied glands before and after involution makes the statement that "The areas of lymphocytosis were much less frequent during and after involution and the areas that were present seemed to be markedly reduced in size" One must recall however, that this observation is based upon seven specimens only

The futility of too enthusiastic generalization on so limited a number of cases is too obvious to require comment Warthin also considers them to be affected when iodine treatment is first instituted, but that they later become increased in size From this, one might be led to conclude that the transitory or partial benefit derived from iodine is in halting further hyperplastic processes in the lymphoid tissue as well as in the epithelial elements of the gland We have previously called attention to the fact that the use of iodine as a therapeutic agent oftentimes so changes the appearance of the gland of exophthalmic goiter as to make the recognition of a definite pathological process next to impossible were one to consider the epithelial elements only While there is no question in our mind regarding the definite pathology exhibited by the thyroid epithelium, we are forced by our own

FIG. 5 Lymphoid tissue in a mild case of exophthalmic goiter

experience as well as by the evidence presented in the literature, to recognize its instability as a pathognomic lesion of Graves' disease in the presence of iodine treatment

We have shown a remarkably close agreement in the clinical diagnosis and the pathological picture when the presence of lymphatic tissue was considered an essential lesion of Graves' disease. Were this lesion to be ignored and the conclusions drawn only from the epithelial hyperplasia and hypertrophy exhibited, a regrettably poor agreement between clinical and pathological findings would result. The presence of lymphatic tissue in practically all glands removed surgically from patients exhibiting undoubted clinical signs of the Graves' syndrome, forces one to consider it a lesion of this disease. We feel that the few cases in which the lesion was not demonstrated represent clinical diagnostic errors or

cases in which the lesion was missed because of insufficient search. In this respect this lesion can be compared to infiltrating malignant cells in the prostate, for instance, where it is oftentimes necessary to section many blocks before carcinomatous areas can be found. Certainly, failure to demonstrate these areas of lymphatic tissue in a few blocks does not warrant a conclusion that they are not present in other portions of the gland. Their persistence after iodine medication confers upon them a major role as a diagnostic lesion inasmuch as we have shown them to be a much more trustworthy indication of hypertrophic and hyperplastic processes than changes in the epithelium.

In the course of a study such as this, one is impressed by the futility of attempting the solution of many of the questions involved by drawing conclusions from a study of dead pathol-

FIG 6 A small area of lymphoid tissue in the thyroid gland of an infant

ogy The problems involved, which are necessary of solution for a clear understanding of thyroid disease, must, in our opinion, be attacked by experimental methods for any reasonable hope of success. Such methods are yet to be devised.

CLASSIFICATION OF THYROID DISEASE

There are many classifications of thyroid disease suggested in the literature, few of which permit both clinical and pathological application. Menne *et al* have proposed perhaps the most extensive workable classification, although it does not coincide with our view that there exists but one process involved in hyperthyroidism, that symbolized by the clinical syndrome of Graves' disease. Warthin proposed a simple classification as follows:

- 1 Simple colloid goiter without Graves' constitution,
- 2 Nodular colloid goiter without Graves' constitution,
- 3 Simple adenoma with Graves' constitution,
- 4 Exophthalmic goiter (Graves' constitution),
- 5 Adenoma with Graves' constitution (so-called toxic adenoma)."

This classification is applicable clinically and is based on the presence or absence of the "Graves' constitution." It recognizes and emphasizes the adenomata in a manner that is to us confusing and not warranted, since it is our contention that the presence of adenomatous areas has no significance in hyperthyroidism. As has been often stated, no classification of any disease is of value that cannot be of clinical as well as pathological application. If the symptoms exhibited by the patient, be they ascribed to Graves' disease, hyperthyroidism, toxic adenoma, or

what not, fit a given syndrome, and there is a constant pathological lesion, one is warranted in assuming the unity of the process. In view of the findings in our study, the practically universal presence of the lesion described as lymphoid hyperplasia, we suggest the following classification and diagnostic scheme:

- 1 Hypertrophic-lymphoid goiter—Graves' disease
 - 1 Epithelial hypertrophy in non-iodized gland
 - 2 Lymphoid hyperplasia
 - 3 If iodized
 - 1 Stroma increased
 - 2 Colloid increased, thin and watery
 - 3 Epithelial hypertrophy may be patchy or lacking
- 2 Nodular colloid goiter
 - 1 Large vesicles containing colloid occurring in pseudo-encapsulated areas
 - 2 No lymphoid tissue or epithelial hypertrophy
 - 3 May show degenerating colloid cysts
- 3 Simple colloid goiter
 - 1 Large vesicles, comparatively uniform
 - 2 No lymphoid tissue or epithelial hypertrophy
 - 3 May show degeneration, cysts, calcification
- 4 Normal thyroid with adenomata
 - 1 Encapsulated areas of "fetal"-like acini or
 - 2 Areas of more developed adenoma
- 5 Inflammatory processes
 - 1 Definite pyogenic infections
 - 2 Tuberculosis, etc
- 6 Malignant new growths

If any thyroid would otherwise fall in the last five groups it will be seen that the presence of lymphoid tissue necessitates placing it in group 1. All the groups become modified by iodination and all may contain adenomatous areas, and in addition there will be the rare specimen usually obtained at necropsy from the potential Graves' patient which will present small areas of lymphoid tissue. These latter cases must necessarily be considered as potential exophthalmic goiter in the absence of clinical signs.

CONCLUSIONS

1 It has been shown that areas of lymphatic tissue occur in the thyroid gland in 28 per cent of infants.

2 This tissue is also found in 2 per cent of thyroids from patients dying from diseases or accidents not involving the thyroid gland.

3 Areas of lymphatic tissue occur in practically all thyroid glands re-

moved surgically from cases of undoubted Graves' disease.

4 The lesion described is not the result of a local inflammatory reaction.

5 The presence of lymphatic tissue in infant and selected necropsy specimens supports Warthin's contention of the existence of a "Graves' constitution", that exophthalmic goiter is the clinical manifestation of a congenital constitutional anomaly.

6 Warthin's conclusion that this lesion is diagnostic for Graves' disease is vigorously supported.

7 Adenomata have no causal relationship to the symptoms of thyroid disease since they occur with equal frequency in normal and pathological glands. The use of the term should be abandoned in connection with the clinical diagnosis of hyperthyroidism.

8 A simple classification and diagnostic scheme of thyroid disease that is clinically and pathologically compatible is suggested.

Pulmonary Lesions in Human Tularemia*†

Pathologic Review and Report of a Fatal Case

By STANLEY D. BLACKFORD, M.D., *University, Virginia*

ALTHOUGH it is well known that tularemia is a blood-borne infection, little notice has been taken of the frequency with which it attacks the lung. Francis¹ reported abstracts of the twenty-four fatal human cases of which he had record up to October, 1928, and in more than one-third of these a diagnosis of intercurrent bronchopneumonia had been made. Simpson² subsequently expressed the opinion that the physical signs in many of these so-called bronchopneumonias were probably due to multiple tularemic necroses. The author³ has recently published the thirteen cases which have come under his personal observation and six of these gave clinical evidence of intrathoracic disease (i.e. pleural effusion, 2, bronchopneumonia, 2, bronchitis, 1, lung abscess, 1).

It seems more than a coincidence that each of the eight cases in which the chest was examined at necropsy should have shown some abnormality of the lungs or pleura. Death in these occurred from four days to five months after the tularemic infection. Simpson² reported "two lesions in the right lung, which were unquestionably

tularemic focal necroses." Palmer and Hansmann⁴ found "an inconsiderable amount of bronchopneumonia which did not give any clinical symptoms." Bardon and Berdez⁵ reproduced a photograph showing tularemic nodules on the visceral pleura of their case and said "both lungs showed an extensive bronchopneumonia." Bunker and Smith⁶ removed twenty-eight ounces of a deep straw colored fluid from the right thorax at necropsy and made a diagnosis of "coagulative necrosis of the right lung." Goodpasture and House⁷ withdrew 200 c.c. of fluid from the left chest postmortem but were unable to find evidence of intrapulmonary damage. Verbrycke's case⁸ had about 100 c.c. of fluid in each pleural space and "multiple areas of caseous necrosis averaging a hickory nut in size" in the lungs. Francis and Callender⁹ quoted a case of Bruecken's dying five months after infection, in which "a calcareous area at the left apex was traced to a multilocular single cavity one centimeter in diameter."

In February, 1931, Massee¹⁰ reported finding physical signs of pneumonia at the bases of both lungs in a case of tularemia dying on the eighteenth day of the disease. At necropsy, gross examination revealed areas of "late red hepatization" in both lungs which were

*From the Department of Internal Medicine, University of Virginia Hospital.

†Received from publication, August 3, 1931.

interpreted as representing a "bronchopneumonia of the confluent type". Numerous short gram-negative bacilli, morphologically consistent with *B. tularensis*, were seen imbedded in the tissue sections. Material from the lung was scratched into the skin of the abdomen of a guinea pig, a granulomatous ulcer developed from which *B. tularensis* was cultured. This case shows that bronchopneumonia may be a manifestation of tularemia rather than a complication of it.

Many writers have remarked on the great similarity of the microscopic pictures seen in the tubercle of tuberculosis and in the caseous necrosis of tularemia, although the comparison has been made mostly in tissues other than the lung. Since the fundamental lesion in both is initially a small area of caseation, this resemblance is not remarkable. It seems peculiar that so little attention has been paid to the similarity of the clinical effects which may be produced by *B. tuberculosis* and *B. tularensis*. Bronchopneumonia, pleural effusion, lung cavitation and lung abscess formation are at least some of the clinical conditions which may be caused by both organisms. One wonders if perhaps a few cases of tularemia have not been mistakenly diagnosed as tuberculosis.

Reference to the microscopic pulmonary lesions in human tularemia are scarce. Simpson¹¹ in his recent monograph on the disease discusses this phase briefly "Foci of caseous necrosis with peripheral epithelioid and fibroblastic proliferations also characterize the hepatic and pulmonary lesions". Stitt¹² paraphrases Francis' description as follows "The lungs present small necrotic foci or white plaques on

the pleura, they contain focal necroses, or there may be bronchopneumonia of any degree, even to the involvement of almost an entire lobe, the alveolar walls are infiltrated with edema and large mononuclears, and the alveolar contents consist of a few leucocytes and red blood cells and a small amount of fibrin". At this time, the criteria for making the diagnosis of tularemia of the lung from pathologic studies alone seem indefinite. Further work is necessary along this line.

The following case is presented because few fatal cases of tularemia have been reported. The pulmonary lesions described are sufficiently similar microscopically to the other cases reported to deduce that the changes in the lungs in this case were due to tularemia. It is felt, however, that they are also sufficiently different to be of especial interest.

REPORT OF CASE

History A negro, aged 38, was sent to the hospital on Dec 6, 1928, from Culpeper, Va. At the time of admission the patient gave an unreliable history but the following facts were supplied by his family physician, Dr J. W. Humphries.

On Nov 4, 1928, the patient, who had had no contact with rabbits during the preceding six months, skinned an opossum found dead in a cage with several live opossums. Four days later his physician was called because of the sudden onset of chills, fever, generalized aching and prostration. The temperature was 102° F. It was observed that the patient's hands "were considerably chapped" although no ulceration was noted. On Nov 11, when the physician called again, the temperature was 103° F and "a suppurative condition around four badly broken front teeth had developed". There was swelling of the glands of the neck. On Nov 16, at the advice of his physician, two of these teeth were extracted under local anesthesia and a "large amount of pus was evacuated". The patient was

able to sit up during the following twenty-four hours, but, on Nov 17, was again forced to bed. On this date, a specimen of blood was sent to the Virginia State Board of Health Laboratory for Widal agglutination and was reported negative. In accordance with their custom of testing all Widal-negative serums with *B abortus* and *B tularensis*, these additional agglutinations were done. The *B abortus* agglutination was negative but the agglutination with *B tularensis* was reported "positive in dilution of 1:40". The agglutination was repeated with a specimen of serum obtained on Dec 3 and was positive with *B tularensis*, 1:5120. The same serum tested by the U. S. Hygienic Laboratory agglutinated in dilution of 1:1280.

On Dec 6, the patient was admitted to the hospital, mainly on account of cough which had developed about two weeks previously. The cough was productive of abundant foul, bloody sputum and was becoming progressively worse.

Examination. The patient was emaciated, obviously ill, sweating profusely, and apparently in stupor. There were many carious teeth with marked pyorrhea and receding gums, and cavities of the two recent extractions. The left axillary glands were slightly enlarged but not tender. The other glands were normal. In spite of a careful search, no ulceration of the skin and no scars were found. There was an old crushed fingernail on the left third finger. The physical signs in the chest indicated fluid or consolidation, or both, in the right lower lobe. Routine examination was otherwise normal. Rectal temperature was 105° F, pulse 120, respiration 32. The blood pressure was 128 systolic, 84 diastolic. Urinalysis was essentially negative. Hemoglobin was 53 per cent (Dare), red blood cells numbered 2,710,000, white blood cells 8,200. The blood smear was typical of secondary anemia and the differential count was 79 per cent polymorphonuclears, 21 per cent lymphocytes. The serum agglutinated *B tularensis* strongly in dilutions of 1:800 and gave an incomplete reaction in dilution of 1:1600. It did not agglutinate *B typhosus* or *B abortus*. The blood Wassermann reaction was negative. The sputum was composed of reddish-brown, bloody, mucopurulent material, no

acid fast or Vincent's organisms were found in six examinations.

Course. The patient remained toxic and at times irrational. His temperature was of the septic type, ranging from normal to 105° F. He coughed up foul bloody sputum, filling one or two sputum cups a day. On Dec 8, an attempt at thoracentesis was unsuccessful. On the 10th, a single bedside chest plate (figure 1) was reported as follows: "The lower half of the right chest shows a marked increase in density which is honeycombed with large irregular areas of decreased density, these have fairly definite borders. The largest of these areas of rarefaction is 6 by 3 cm and occupies the space between the sternal ends of the second and fourth ribs. The appearance on the left is that of rather heavy hilus shadows. This region is also thickly studded with small round areas of calcium deposit."

Conclusions. Lung abscesses, right, probable bronchiectasis, left. The patient continued to become more toxic and died from general toxemia on Dec 15, 1928.

Necropsy Examination. was performed three hours after death by Drs. Harry T. Marshall and Joseph B. Graham.

The pleural cavities contained no fluid. The anterior aspect of the right lung was normal. The middle lobe was adherent to the upper lobe and partially so to the lower. Posteriorly the lung was bound down by extensive and firm adhesions at the base. On removing the right lung a cavity was encountered where the lung had been attached. This cavity was 8 by 12 cm and extended from the diaphragm to within a centimeter of the top of the lower lobe. It seemed as if the anterior wall was formed by rough, irregular, dirty gray, necrotic lung tissue, and the posterior wall by the visceral pleura which was adherent to the chest wall. This cavity contained about a pint of foul, purulent, bloody fluid. A probe passed down the main bronchus failed to communicate with this cavity. On section a large friable thrombus was found almost obstructing the lumen of the right pulmonary artery, numerous thrombosed arterioles were seen.

The left lung was congested in spots but elsewhere was pale. It was somewhat emphysematous. A slightly darker region occurred in the upper lobe, the pleura was lit-

tle involved over this area. A thrombus was found partially filling the pulmonary artery at the hilus. The outer wall of the thrombus was more pliable and the center was softer than in the right lung. Section through the consolidated area showed multiple thrombi.

In the angle of the bifurcation of the trachea there was a walnut sized mass of lymph nodes, which were coherent, soft and under tension. On section, there was much pigment deposit and three or four very small pearly spots which did not project above the surface.

The pericardium and heart appeared grossly normal except for a cloudy swelling of the myocardium. Both the spleen and liver failed to reveal any lesions suggestive of tularemia either on the surface or on section. The liver was of the fatty, nutmeg variety and the spleen resembled an acute splenic tumor of the septicemic type. The kidneys were cloudy and congested. The other viscera were normal.

Histologic Study The microscopic sections were studied by Dr. Thelma Brumfield, who had at her disposal material loaned by Dr. Edward Francis from two of the cases reported by Francis and Callender. After a comparison of these with those from

this case, Dr. Brumfield felt justified in saying that the lesions in this case were due to tularemia. The significant features were found in the sections from the axillary and bronchial lymph nodes, the lungs and the liver. Dr. Brumfield's reports on these are quoted in detail.

"Left Axillary Lymph Node" In this section were two small areas with a central coagulative necrosis, surrounded by large mononuclear epithelioid cells and a zone of fibroblasts. No Langhans cells were seen but these two areas closely resembled tubercles. The germinal centers from other areas of this node were pale and the sinusoids contained numerous large mononuclear cells. Eosinophils were relatively abundant. Another section contained no necrotic areas and no other unusual changes except hyaline degeneration of small blood vessels.

"Hilus Lymph Nodes" There were three areas of coagulative necrosis similar to those already described except that they lacked such definite zones of epithelioid and fibroblastic cells. The other lymph nodes examined were apparently normal.

"Right Lung" One section revealed in a medium sized artery an occluding thrombus containing many clearly outlined red blood cells. This appeared to be a propagated

FIG 1 Retouched bedside film taken December 10, 1928, showing cavities in right lung

thrombus though it seemed to be partially attached to the vessel wall. In the adventitial tissue surrounding, there was a striking accumulation of mononuclear cells and a proliferation of fibroblasts in which were a few well preserved polymorphonuclear cells. The smaller vessels of this area were congested with red blood cells. Just outside the adventitial tissue the alveoli contained many large mononuclear cells. In this area there were a few spaces containing semincretic exudate, composed chiefly of mononuclear cells and some polymorphonuclears. The remainder of this section showed a diffuse widespread necrosis of the lung tissue. This resembled closely a caseous pneumonia, since within the necrotic alveolar exudate were still retained the outlines of large mononuclear cells without pus formation, and only a moderate degree of hemorrhage. Gram-Weigert stain was negative for organisms in this tissue. Another section, adjacent to the large abscess cavity, contained a few air-bearing alveoli with thickened walls, and numerous microscopic nodules of consolidated lung tissue, the centers of which were necrotic, resembling early tubercles and surrounded by epithelioid cells and collagen fibers. In the same section was an area of profuse hemorrhage into the lung tissue in which appeared numerous areas of coagulative necrosis. Histologic details here were obscured by the hemorrhage. Gram-Weigert stain was negative.

"Other sections from the wall of the abscess showed marked proliferation of fibro-

blasts with collagen production, thick walled vessels, and an exudate of mononuclear and polymorphonuclear cells. Several small arteries revealed a proliferative endarteritis.

"Two minute areas of necrosis surrounded by large mononuclear cells were seen in the sections from the liver."

SUMMARY

The reported effects of *B. tularensis* on the human lung are reviewed and attention is called to the probable frequency and importance of these pulmonary manifestations. A case with necropsy is presented with the following observations of interest: (a) the probable source of infection was an opossum, (b) the clinical diagnosis of pyogenic lung abscess was discredited by microscopic study of the tissue, (c) the pulmonary damage was extensive and of prime importance as a cause of death, (d) the multiple pulmonic thrombi, with attending areas of necrosis were probably attributable to the tularemic infection, and (e) gross caseous nodules were lacking in the liver and spleen.

Two additional reports^(13, 14) of pulmonary lesions in human tularemia have appeared since this paper was written.

Oliver Goldsmith, M.D.*

By LOUIS H. RONDIS, M.D., Lieutenant Commander, Medical Corps,
U S Navy

WITH no other medical poet is the dignified doctoral prefix more commonly employed. He was "Dr. Goldsmith" to Boswell and the Johnson circle, and his contemporaries almost without exception referred to him as the "Doctor" yet the medical side of Goldsmith's life has been rather neglected, though it is both a considerable and interesting subject. The circumstances of his medical education, his attempts to practice in Southwark and in London, his relation to one of the celebrated nostrums of the day, and its use in his last illness are all well attested though not commonly known facts.

His biographers are unable to decide with certainty whether Oliver Goldsmith was born in the village of Pallas or the village of Elphin, Roscommon, Ireland. The year of his birth is also in doubt, though it was probably 1728. This is the date inscribed in the tablet in Westminster Abbey. Curiously enough the day of his birth, November 10, is the best authenticated of these three facts regarding the place and time of his appearance in the world. His father, the Reverend Charles Goldsmith, was a poor country curate. His son has immortalized his kindly

and guileless character in the "Vicar of Wakefield" and he was also the original of the clergyman of the "Deserted Village", "passing rich on forty pounds a year".

When Oliver was seven years of age his father's circumstances were improved by the gift of the living at Kilkenny West, and the family moved to the parsonage on the outskirts of the pretty little village of Lissoy not far from Athlone. Lissoy is celebrated as the "Sweet Auburn, loveliest village of the plain" and its rural beauties are pictured in the opening lines of the "Deserted Village".

Goldsmith attended the school at Lissoy kept by an old pensioned soldier, full of stories of Marlborough's wars and the whimsical legends of Celtic Ireland. He must have influenced the imaginative mind of the boy destined to be one of the greatest of English poets. There was little in Oliver's appearance however to indicate a brilliant future. He was homely to the point of positive ugliness, awkward, loose jointed and undersized. Smallpox, from which no one before the time of Jenner escaped, had further disfigured his countenance. A peculiar guilelessness and simplicity of character was an additional incitement to making him the target for all sorts of ridicule.

* Received for publication, October 12, 1931

At seventeen he was packed off to Trinity College, Dublin, where he was entered as a sizar or poor student. On one side of the entrance gate fronting on College Green, Trinity has erected a noble statue to this poor sizar who was to be considered by the world as one of her most famous sons, no small distinction as Trinity was also the Alma Mater of Edmund Burke, Dean Swift, Bishop Berkeley, and Thomas Moore.

Goldsmith's college career was rather stormy. He was one of those good hearted, good natured, heedless persons, easily led, and loving gayety and conviviality. Once he was expelled for participating in a riotous party within the precincts of the college. His scholarship, too, does not seem to have been very remarkable but he was finally graduated on February 27, 1749, O S, with the degree of Bachelor of Arts. The next three or four years were spent in fixing upon a profession. He attempted to take holy orders but was rejected by the Bishop, some say because of failure to pass the requisite examination, others because he presented himself to the Bishop arrayed in scarlet breeches. It was decided that he should study law and he was equipped with a new outfit of clothes, a good horse and thirty pounds. In a few months he returned with a single rusty suit, a broken down pony, and one shilling. He now lived for a time with his indulgent uncle Contarine, and made good progress in learning to play the flute and fiddle and in writing verses, accomplishments that pleased his uncle and a pretty cousin, but did not help him in securing an honorable or independent position in the world.

Most of the Goldsmith family were

poor and improvident. There was one notable exception. This was Dean Goldsmith who was the incumbent of a rich deanery and whose position and material wealth made him an oracle to his poor relatives. He appears to have asked "Why not make Oliver a physician?"

The suggestion of a great man like the Dean could not be disregarded and in the Autumn, of 1752, Oliver was entered at the University of Edinburgh as a "Student in Physic" to use his own words. As a medical student he had an experience in respect to his first boarding house that all other indigent medical students will appreciate. The table was furnished like that of Don Quixote, whose weekly menu consisted of "Soup composed of somewhat more mutton than beef, the fragments served up cold on most nights, lentils on Fridays, stew on Saturdays, and a pigeon by way of addition on Sundays." The similarity of this diet to that of Goldsmith's boarding house is shown by his description of what could be done to extend a loin of mutton throughout the week. "A branded chop was served up one day, a fried steak another, collops with onion sauce a third, and so on until the fleshy parts were quite consumed when finally a dish of broth was manufactured from the bones on the seventh day, and the landlady rested from her labors."

He spent two winters in Edinburgh where he made a better reputation as a story teller and good fellow than as a student. However, he took a particular interest in chemistry and had for his professor, Joseph Black, the discoverer of carbonic acid gas, who remembered Goldsmith as a promising pupil. Another of his teachers was

Alexander Monro, senior, the celebrated anatomist

Goldsmith's fondness for dress and his vanity have been frequently noted. A tailor's account, while he was a medical student, is full of rich colors and fabrics. "To 2½ yds Sky-Blew satin, at twelve shillings a yard, To ¾ yds fine Sky-Blew Shalloon, 1 s yd, To a fine small hat 14 s, To 1 oz 6¼ dr silver hat lace, 8 s, to a pair fine thd black hose, to 3½ yds best fine

high claret colored cloth, 19 s" So Goldsmith was not illy dressed during this period and furthermore the tailor's ledgers show that he paid his bill.

Although the University of Edinburgh was, and is today, one of the most famous medical schools of the world Goldsmith quitted it after two years to make a tour of the Continent. In a letter to his good natured uncle Contarine, who financed him to some

FIG 1 Oliver Goldsmith, M D

degree in his medical studies, he says "I intend to visit Paris where the great Monceau instructs his pupils in all the branches of medicine and the next winter go to Leyden. The great Albinus is still alive there and 'twill be proper to go through only to have it said that we have studied in so famous a University."

Goldsmith's real reason for going abroad was no doubt his desire to see the Continent. Edinburgh was scarcely less celebrated as a medical school than Leyden, yet he well describes the advantages that take the student to another country to carry on the same studies as at home. To be able to say that one has been at a famous foreign University, the professional contacts in other lands and cities, the experiences of travel are valuable acquisitions not to be obtained in any other way, and the world takes note of these things and the returning student finds that he has an added prestige not possessed by the stay-at-home classmate.

In February, 1754, Goldsmith took up his studies at Leyden and no doubt attended the lectures of Albinus, one of the greatest of anatomists and professor at Leyden for more than fifty years. It is pretty evident, however, from certain descriptions he has given of the fair sex both at home and abroad that his studies were not all of a professional character. In one of his letters to his uncle Contarine he compares the Dutch and Scottish types of femininity. "The Dutch woman and a Scotch will bear comparison. The one is pale and fat, the other lean and ruddy, the one walks as if she were straddling after a go-cart, and the other takes too masculine a stride. I shall

not endeavor however to deprive either country of its share of beauty."

He had arrived in Holland with 33 pounds sterling and borrowed money from another Irish student, Ellis, afterwards a physician of some note, when he left Leyden and began his travels through France, Switzerland, and Italy. According to his own account much of the journey was on foot and he often stayed at the houses of peasants, paying for food and lodging by playing the flute or telling amusing stories of his adventures. The journey was begun in 1758 and lasted about one year. During it he visited Louvain, Paris, and Padua. It was from the University of Louvain that he is supposed to have received the degree of Bachelor of Medicine, a title first used in connection with his name in 1763, when it is appended to one of the Dodsley agreements. Many of the records of Louvain University were destroyed during the French Revolution so that documentary evidence was not available when Prior and Washington Irving attempted to examine into this subject. Macauley expresses his doubts that Goldsmith ever obtained a medical degree, and indeed intimates that, like all travelers, he drew the long bow pretty generally. Goldsmith himself tells of having seen Voltaire in Paris and describes a conversation with him in most circumstantial terms, though it is now known that Voltaire was not at the time within a hundred leagues of Paris so that Macauley's doubts are not ill founded. Though the question of the medical degree from Louvain cannot be settled other than by a Scotch verdict of "not proved", the general use of the title of "Doctor", Goldsmith's use of the term "Bachelor

of Medicine", and his claim that this degree was received from Louvain must carry weight

Goldsmith returned to England in 1756, penniless and friendless. His uncle Contarine, who had been his patron and who had interested himself in his nephew's behalf on all occasions, was dead. For a time his circumstances were desperate. He slept in the streets and consorted with beggars. He attempted unsuccessfully to obtain employment in an apothecary shop. He did however obtain a place as usher in a private school but left it to become the assistant of a chemist. There, through the assistance of a fellow student at Edinburgh, Dr Sleight, he commenced the practice of medicine at Bankside, Southwark. He starved here, too, though he told another old college companion, Beatty, who met him at this time, that "He was practising Physic and doing well". Dr Farr, who had also been with him as a medical student, says that when he met Goldsmith at this time the poet was clothed in a coat of rusty black velvet with a patch over the left breast, an evidence of poverty that he concealed by holding his three-cornered hat over it.

Dr Sleight introduced Goldsmith to Richardson, the novelist and bookseller, who gave him some literary hack work to do and it was thus that he began his career as a man of letters. His work soon attracted the attention of Dr Samuel Johnson and through his friendship Goldsmith became a member of the famous literary club, the record of whose meetings has been so completely reported by Boswell. It is of interest that two of the original members of the club were medical men for, in addition to Goldsmith, the membership included Dr Nugent, the father-in-law of Edmund Burke, a Roman Catholic, and a successful and highly respected physician.

Both Johnson and Sir Joshua Reynolds recognized Goldsmith's genius. Hawkins says that he was looked at askance by some of the other members "as a mere literary drudge equal to the tasks of compiling and translating but little capable of original and still less of practical composition".

This view was changed by the publication of "The Traveler" and the "Vicar of Wakefield". The former has been declared with good reason to be the finest poem in English since the appearance of Pope's "Essay on Man".

FIG 2 An autograph receipt by Oliver Goldsmith, M.D

and the excellence of the "Vicar of Wakefield" has been attested by successive generations of readers

The years that followed were probably the most successful and happy of Goldsmith's life. He enjoyed the praise of "The Traveler" and the "Vicar", and the admiration excited by "The Deserted Village", perhaps the finest pastoral poem in English. These years also saw his success as a playwright with the comedies of "She Stoops To Conquer" and "The Good Natured Man"

He was frequently the guest of Reynolds, Mrs Thrale and Mrs Vesey. The given name of Mrs Vesey's husband was Agronisham and we can gain some idea of the fame of the Johnson circle at this time when we find that Agronisham Vesey, though wealthy and socially prominent, was so concerned over his entrance into the Literary Club that the night his name came up for discussion he had a relay of foot messengers to bring the news of his election and was much agitated until he found that he had been accepted for membership. At Sir Joshua Reynold's, Goldsmith met the Hornecks and fell in love with the younger daughter celebrated as the "Jessamy Bride". His financial affairs, though always in a tangled state due to his improvidence, were nevertheless better than at any other time in his career and he appears to have enjoyed an income of four or five hundred pounds a year. This is the time of the "bloom-colored coat" mentioned by Boswell.

Three features of Goldsmith's medical life should be noted. The first of these was his attempt to gain a medical appointment in India. This attempt was successful and he was appointed

physician and surgeon to one of the factories of the East India Company on the Coromandel Coast. The appointment was worth fifteen hundred pounds a year, a very large sum for those days, partly in salary and partly in fees and perquisites. It was necessary that he pass a professional examination and make a deposit toward his passage money before he was finally accepted for the post. He probably failed in one of these requirements for he was never actually appointed and none of his friends could learn from him the real reason for the final failure of the scheme.

Goldsmith had always a great interest in the Orient and in 1761 he drew up a memorial to Lord Bute in which he suggested a scientific mission to Aleppo, of which Goldsmith was to be the head, to inquire into the useful arts, inventions, and customs of the East with the idea of bringing back to Europe methods unknown there. The Government paid no attention to the memorial except to disapprove it. No one could have been more unsuited than Goldsmith to lead such an expedition as Dr Johnson pointed out in one of his characteristic pronouncements. "Of all men" said he, "Goldsmith is the most unfit to go upon such an inquiry. Sir, he would bring home a grinding barrow, which you see in every street in London, and think that he had furnished a wonderful improvement."

After the failure of his India appointment, he sought to be examined for a surgeon's mate in the Army. Records of the College of Surgeons showed that he appeared for examination at Surgeon's Hall, December 31, 1758, and was found *not* qualified.

In spite of this, in 1765 after the

publication of "The Traveller" his social and financial prospects were much changed for the better, and Sir Joshua Reynolds, always Goldsmith's sincere well wisher urged him to resume the practice of medicine and pointed out the advantages he could obtain from being known as the member of such a profession. It must be remembered that in eighteenth century England the social position of the physician was high, the large number of men of family and talent from Harvey and Sydenham to Meade, Garth and Arbuthnot in the medical fraternity having done much to bring it to a high plane. Goldsmith therefore took his friends advice and began again as a medical practitioner under more favorable circumstances than surrounded him in his first attempt. He was now a man of note in the world of letters, had many powerful friends, and was no longer pressed for funds. In spite of these advantages his practice did not flourish as he himself quickly tired of the restraints and responsibilities imposed by his profession. Most of his patients were among those who forgot to pay him and his fees in consequence did not come up to his expectations. Finally an apothecary questioned the dosage of a drug prescribed by Dr Goldsmith, and in the dispute the patient, a Mrs Sidebotham, sided with the pharmacist to the disgust of the Doctor who left the patient and practice in a passion. To Beauclerc he said, "I am determined to leave off prescribing for my friends." "Do so, my dear Doctor", answered the wit, "whenever you undertake to kill, let it be only your enemies."

Goldsmith's last illness and death

were attended with circumstances that led to considerable controversy at the time. The poet had suffered in 1772 from an attack of dysuria which may have been due to an old Neisserian infection, though it may of course have been a non-specific condition. At this time he had been treated by Dr James, a respectable physician of the day who was the author of a three volume Medical Dictionary, but is best known, however, by a secret prescription sold everywhere as "James' Powder". The sale of this powder made him rich. It was then common for remedies to be kept secret by reputable medical men so that his conduct was not as unethical as it would be considered today. The powder was a compound of calcium phosphate and antimony oxide, and was diaphoretic, emetic, or purgative in its action depending on the dose used. It survives now in the National Formulary as the pulvis antimonialis, or James' powder, where the dose is given as 0.2 gram or 3 grains. Goldsmith had used this remedy under James' direction with relief of his symptoms and had apparently conceived an exaggerated idea of its value. In the early part of 1774 he had an exacerbation of his cystitis and his general health seems to have been impaired. He became quite ill on March 25, and sent for Mr Hawes whose account was published shortly after Goldsmith's death.

The following is the narrative of Mr Hawes.

"On Friday, the 25th of March, at 11 o'clock at night, the late Dr Goldsmith sent for me to his chambers. He complained of violent pain extending all over the forepart of his head, his tongue was moist, he had no cold

shiverings, or pain in any other part, and his pulse beat about 90 strokes in a minute. He then told me he had taken two ounces of ipecacuanha wine as a vomit, and it was his intention to take Dr James' Fever Powder. I replied that, in my opinion, this was a medicine very improper at that time, and begged he would not think of it. But I am sorry to say that every argument used seemed to render him more determined in his opinion; which gave me much concern, as I could not avoid thinking that the man whom I had every reason in the world to esteem was about to take a step which might prove extremely injurious to him. I therefore endeavoured to reason medically with him and observed that his complaint appeared to be more a nervous affection than a febrile disease. However, though I reasoned with him on the subject for near half an hour by his bed-side, and vehemently entreated him not to take Dr James' Powders, yet I could not prevail upon him to say he would not. At least I addressed him, to the best of my remembrances in the following manner:

"Please, Sir, to observe, that if you do take the fever powder, it is entirely without my approbation, and, at the same time, remember how very anxious I have been to persuade you to desist from doing it, and now I will take my leave, if you will be kind enough to grant me one request." He very warmly asked me what that was. I told him that, as he had always consulted Dr Fordyce in preceding illness, and had expressed the greatest opinion of his abilities as a physician, I hoped he would permit me to send for him. It was full a quarter of an hour before I could obtain his consent to this, as the

taking of Dr. James' powders appeared to be the only object which employed his attention, and even then he endeavoured to throw an obstacle in the way, by saying that Dr Fordyce was gone to spend the evening in Gerrard Street, 'where', added he, 'I should also have been, if I had not been indisposed'."

Fordyce, an M D from Edinburgh in 1758 and a member of the Johnson circle, now took over the case but not until the poet had obtained from Hawes some James' powders which on taking he declared were not of proper composition and made him worse. He continued to grow worse, and became very drowsy and weak with a pulse ranging from 120 to 140 and an irregular low temperature.

On Sunday night, April 3, he fell into a deep sleep, at four o'clock in the morning of April 4, he was seized with a convulsion and expired an hour later.

His death was thus announced in the *Public Advertiser* of April 5: "Yesterday morning died, much and deservedly regretted, at his chambers in Brick Court, in the Temple, Dr Oliver Goldsmith, author of the poems of the *Traveler*, and *Deserted Village*, and many ingenious works in prose. He was seized on Friday night with a nervous fever in his brain, which occasioned his death."

A considerable controversy arose as to what effect the popularly used James' Powder had on the course of his illness, some declaring that it had hastened his end, others defending it. A rumor arose that Dr Goldsmith believed that there had been a mistake in the compounding of the powder and this rumor became so troublesome that

Hawes published a brief account of the affair, apparently to defend himself against gossip

Just what the exact diagnosis was is not known but it is clear that an infection of the genito-urinary tract was the basic condition and the injudicious use by the patient, against the advice of his medical attendant, of a powerful irritating emetic and purgative produced a gastro-enteritis as well. Hawes and, indeed, all the medical men who attended Goldsmith, appeared to have done all that was possible.

Hawes became a man of mark, was a friend of Reynolds and of Goldsmith and the fact that he managed the latter's affairs and disposed of his effects after the poet's death indicates that Goldsmith's friends did not consider him remiss in any important particular. Hawes was made a Doctor of Medicine in 1780. He died at his birthplace, Islington, in 1808.

Goldsmith's death excited very little attention among the public as a whole but there was a general mourning among all his friends and associates to whom his simplicity and kindness of heart greatly endeared him. If one were to attempt to convey an idea of this good natured friendliness in a single incident it could perhaps be best done by quoting the concluding line of one of his letters to a member of a country family. After asking that his respects and regards be given to the members of the family he adds "And if there is an old dog in the family pat him on the head for me"

After Goldsmith's coffin had been closed it was opened again at the urgent request of the Jessamy Bride, the lovely Mary Horneck, that she might cut off a lock of his hair. This memento

of the poet she treasured through her long life (she did not die until 1840) and the memory of her affection and devotion have in the words of Irving, "hung a poetical wreath above her grave"

Sympathy and kindness were nearly the only attributes that Goldsmith possessed that fitted him for the practice of medicine. In all other respects few could have been so unfitted by nature for so exacting a profession. He was careless and impatient of restraint, with little idea of responsibility. His knowledge was of a miscellaneous and impractical kind and he never seems to have been a serious student.

As both a poet and a prose writer Goldsmith holds a high place in English literature. His smooth and flowing prose is unsurpassed by any English writer, except Addison, and his graceful verse was distinguished in a literary age celebrated for the quality of its poetry.

A little known fact regarding Goldsmith is the influence his writings had upon the life and work of Goethe. This influence is to be distinctly seen in Goethe's thought and life and was acknowledged by him in terms that deserve to be repeated. He expressed it strongly in his autobiography and in 1830 when he was eighty-one years of age, in a letter to Zelter he said "It is not to be described, the effect that Goldsmith's *Vicar of Wakefield* had upon me, just at the critical moment of mental development. That lofty and benevolent irony, that fair and indulgent view of all our infirmities and faults, that equanimity under all changes and chances, and the whole train of kindred virtues, whatever names they bear, proved my best edu-

cation, and in the end they are the thoughts and feelings which have reclaimed us from all the errors of life" Further he mentions that he has recently read "the charming book again from beginning to end" As Foster expresses it "The strength which can conquer circumstances; the happy wisdom of irony which elevates itself above every object, above fortune and misfortune, good and evil, death and life, and attains to the possession of a poetical world, first visited Goethe in the tone with which Goldsmith's tale is told"

Johnson, who at times had borne an

almost parental relation to Goldsmith, scolding him for his shortcomings in the parental style, loved him and felt his death the most keenly of any of the warm circle of friends with the possible exception of Sir Joshua Reynolds It was Johnson who composed the epitaph inscribed on a marble tablet beneath the medallion bust in the Poets' Corner of Westminster Abbey, beginning,

Editorial

THE NATURE AND ETIOLOGY OF HODGKIN'S DISEASE

Aside from the reported discovery of various organisms in the involved tissues in Hodgkin's disease, the implication that this condition is of infectious origin has been found in histological rather than clinical evidence. Neither geographical distribution nor age and sex incidence points in any significant way to a parasitic etiology. Of epidemiological aspects there are none save the not infrequent appearance of Hodgkin's disease in more than one member of a family, but this occasional observation is far less impressive than the familial incidence of certain other diseases, such as the retinal neuroblastoma, for instance, in regard to the neoplastic nature of which there is no difference of opinion. Also, when the invariably fatal outcome is considered in connection with the non-vital character of the structures first giving clinical evidence of involvement, no support for a belief in an infectious origin can be found. With those infectious diseases which entail the highest mortality, at least an occasional victim survives.

From the histopathological standpoint, however, Hodgkin's disease presents features which strongly suggest an infectious granuloma. Such are the variety of the microscopical changes and particularly the simultaneous occurrence of multiple cell types, lymphoblasts, fibroblasts, eosinophils, and var-

ious giant cells, all tending as the process advances to give way to a mature or hyaline fibrosis on the one hand, or to pass into caseation necrosis on the other. It was some years ago that the writer was warned by the distinguished director of a certain European pathological institute to be particularly careful in the postmortem examination of a case of Hodgkin's disease, because "young men are especially susceptible to the infection." The sincere solicitude of the advisor was appreciated, but without conviction as to the gravity of the danger. Yet it must be acknowledged that the complex histopathology of Hodgkin's disease does invite the assumption that this disease is a chronic infectious granuloma, a view which is still entertained by many competent pathologists.

The recent work of L'Esperance¹ has encouraged those committed to the parasitic etiology of Hodgkin's disease, especially since Ewing has given some measure of support to this view. L'Esperance believed that the tubercle bacilli which she obtained from a case of Pel-Ebstein disease were of the avian type. From these studies she deduced that the avian tubercle bacillus probably has an etiological relationship to Hodgkin's disease. Is this but another episode in sequence with the many assertions and suggestions which have

¹L'ESPERANCE, E. S. Study of case of Hodgkin's disease in a child, Jr Immunol, 1930, xvi, 127-132

gone before? Tubercle bacilli of strains unspecified, diphtheroids, pleomorphic cocci, amebae, and monilia have each been given a rôle, playing an aggressive or a timid part depending upon the degree of caution possessed by their respective proponents. The very multiplicity of these claims raises doubt that there is a parasitic cause, while many who believe that Hodgkin's disease is infectious in nature are driven to the conclusion that the etiological agent has not yet been discovered.

Through an experimental and analytical investigation Medlar² has advanced well-considered and significant opinions in respect to the changes and responses of the hematopoietic and lymphoid tissues to infection with the avian tubercle bacillus, and in regard to the essential nature of Hodgkin's disease. He found that the histopathology induced by intravenous infection of normal and of vaccinated rabbits with virulent avian tubercle bacilli was not significantly different from that produced by other types of tubercle bacilli. The differences in gross and microscopic pathology caused by tubercle bacilli of the avian, bovine and human types are to be explained by differences in virulence, in susceptibility and in dosage, and are not specific for type of infecting organism. The important differences produced by the avian bacillus in vaccinated and non-vaccinated animals demonstrated this point. In

normal rabbits infection with avian bacilli produced constant lesions in the bone marrow. Among these were discrete collections of mononuclear leucocytes, sometimes necrotic, with varying degrees of infiltration with neutrophils. The hematopoietic tissue of the marrow was always hyperplastic, with numerous mitotic figures and increased megakaryocytes. Coincident with these changes in the marrow, there was an increase in the circulating mononuclear leucocytes. The megakaryocyte seemingly plays an important rôle in acute avian tuberculosis in the rabbit.

These observations of Medlar bring to mind those occasional examples in man in which a blood picture simulating an atypical leukemia is produced by an overwhelming miliary tuberculosis. One case known to the writer was believed to be an unusual leukemia on the basis of the increased number and preponderance of young mononuclear cells in the circulating blood. At autopsy rupture of caseous bronchial nodes into a pulmonary artery was demonstrated, and the bone marrow showed countless miliary foci of necrosis and young tubercles.

In Medlar's animals which had been infected intravenously with virulent avian tubercle bacilli, there were no gross pathological lesions simulating Hodgkin's disease. Microscopical examination showed in the lungs, liver and spleen a few to many giant cells which were indistinguishable from the giant cells seen in Hodgkin's lesions. The bone marrow in these animals was markedly hyperplastic and showed a marked increase of megakaryocytes. These were found in the process of entering the circulation as well as within

²MEDLAR, E. M. Avian tuberculosis in normal and vaccinated rabbits, *Am. Jr. Path.*, 1931, vii, 475-489. The significance of lesions resembling Hodgkin's disease in tuberculosis, *ibid.*, 491-497. An interpretation of the nature of Hodgkin's disease, *ibid.*, 499-513.

the blood sinuses of the marrow. These findings led to the conclusion that the giant cells observed in the tissues were also megakaryocytes. These lesions, suggestive of Hodgkin's disease, were not found in animals, which, by reason of smaller dosage or partial protection through vaccination, were able to survive for several months or longer. Moreover, essentially the same lesions were produced in experimental animals inoculated with virulent bovine and human tubercle bacilli, when the course of the disease was rapid but not when death occurred after a longer interval. Thus it appears that the avian organism has no monopoly on the production of this type of reaction. The megakaryocytes in the acutely tuberculous animals Medlar found to be closely similar to the Sternberg giant cells of Hodgkin's disease. But the presence of megakaryocytes in the circulation and lodged as emboli in the capillaries of the lungs is not a condition peculiar to acute tuberculosis. It is not specific for any condition, but occurs in various toxic and infectious states.

Medlar never observed the pleomorphism of cells or the other cellular appearances of true Hodgkin's disease in his experimental animals, and concluded that not only is Hodgkin's disease not produced by any type of tubercle bacillus but that no infectious agent can be the etiological factor. On the contrary his investigations led him to the belief that Hodgkin's disease is

a malignancy of the bone marrow for which the megakaryocyte is the type cell, and that the characteristic histopathology of Hodgkin's disease is explainable as a pleomorphic aggregation of cells which represent the developmental cycle of the megakaryocyte. The origin of lesions outside of the bone marrow he believed to be due to metastasis. The term "megakaryoblastoma" was suggested to designate true Hodgkin's disease.

The new element in Medlar's analysis is the designation of the megakaryocyte as the stem cell for the origin of Hodgkin's disease and the consequent localization of a primary focus in the bone marrow. It will not be easy to prove that the process by which the disease becomes generalized is one of metastasis and not simply the manifestation of a neoplastic system dyscrasia. May it not be true that cells potentially capable of giving rise to premegakaryocytes are to be found widely distributed in the reticulo-endothelial system outside of the bone marrow? The 'myeloid' reaction is seen in many situations in the body, such as the submucosa and subserosa of the bladder, for instance, where it appears to have arisen *de novo*. At any rate, these stimulating papers by Medlar give added support to the view that Hodgkin's disease is a neoplastic process genetically related to lymphoblastoma, myeloma, chloroma and the leukemias.

The Plantar Reflex, its Significance, the Methods of its Examination and the Causes of Some Diagnostic Errors By THEODOR DOSUZZKOV, M D (The Jr of Nerv and Ment Dis, 1932, LVV, 374-383)

The plantar reflex should be examined with the patient in the dorsal position, with his extremities extended and with the feet resting on the heels. A blunt needle or a pin should be the instrument used and never an object with a wide end, such as the handle of the neurologic hammer. In making the examination the pin should be traced slowly along the internal and external edges of the foot-sole from the heel to the elevation above the metatarsophalangeal joint, but not on that elevation. The reactions that are to be observed are (1) movement of the toes, (2) tension of the 'm tensoris fasciae latae', (3) movement in the big joints (talocrural, knee and hip). The movement of the toes has been the most studied. Its normal display, plantar flexion and adduction, is present in from 88 per cent to 98 per cent of normal persons in various series studied. The modifications of this reflex can be both quantitative and qualitative. Of the qualitative modifications inversion is the most important, but of this 'Babinski's phenomenon' there exist several varieties. The complete form displays itself in the dorsal flexion of all five toes. A frequent form is that of dorsal flexion of the first toe and plantar flexion of the other four. This is the form frequently meant when the presence of Babinski's phenomenon is mentioned in case reports. Other forms are dorsal flexion of the first toe or of all toes, appearing upon irritation of the external side only of the sole of the foot, while irritation of the internal side produces the normal reflex, and inconstant inversion of the reflex, alternating with the normal form of plantar reflex or with its entire absence. All of these phenomena have the same significance. They

practically always mean a lesion of the pyramidal system. Diagnostic errors dependent upon the plantar reflex fall into two main groups. One of these is derived from technical faults of which the most common are an incorrect position for the patient during the examination, the use of an unsuitable instrument (usually the handle of a neurologic hammer), and the examination of the reflex from the part of the sole of the foot below the toes (by which method the positive Babinski's phenomenon may be caused to appear in healthy persons). The other group depends upon incorrect appreciation of properly obtained facts. Here the chief cause of error lies in ignoring the 'physiological Babinski', 'peripheral Babinski', 'pseudo-Babinski', 'pseudo-Puusepp', and 'pseudo-pathological Babinski'.

"Bothriocephalus Anemia" — Diphyllobothrium Latum and Pernicious Anemia By IVAR W. BIRKELAND, M D (Medicine, 1932, XI, 1-139)

The fish tapeworm has been reported in more than 250 cases of infestation of human beings on the continent of North America. At least twenty-three cases have been reported in patients who have spent their entire lives in this part of the world. The frequency of infestation is increasing so that the fish tape-worm is now estimated to be the most common cestode in the North-Central States and Central Canada. In New York City, as well as in Chicago and Minneapolis, the numerical predominance of this parasite over the pork and beef tapeworms has been recognized. While a majority of those harboring the fish tapeworm suffer no ill effects therefrom, some show a variety of clinical manifestations without anemia, with symptoms referable to the central nervous system or to the alimentary tract. In nonanemic carriers there may be noted an altered blood picture which has been defined as an abortive form of *Diphyllobothrium anemia*. When

present, the fully manifest anemia runs true to type with but very few exceptions, and as a rule it is indistinguishable from cryptogenetic pernicious anemia, clinically, hematologically, and pathologically. Achlorhydria is present in about 84 per cent of cases of *Diphyllobothrium* anemia. When hydrochloric acid is present, the acidity is usually below the average level. The incidence of spinal cord changes in association with this type of anemia has not been thoroughly investigated. Numbness and tingling in the hands and feet are not uncommon complaints. Prior to the recognition of the etiologic significance of the tapeworm in relation to this anemia, the same grave prognosis prevailed as for cryptogenetic pernicious anemia until the introduction of treatment with liver. Systematic anthelmintic measures have greatly reduced the mortality, and the cure of the anemia thus obtained is remarkably permanent. Since in Finland only one of 5,000 to 10,000 carriers of this worm develops a definite anemia, it is obvious that the worm cannot be the sole factor involved in the production of the anemia. Peculiarities of the constitution—racial, familial, and individual—must have to do with the ultimate susceptibility which makes the development of this type of anemia possible. This means a specific predisposition for the development of anemia of the pernicious type.

The National Leper Home (United States Marine Hospital), Carville, La. Review of the More Important Activities during the Fiscal Year Ended June 30, 1931. By O. E. DENNEY, F. A. C. P., Surgeon, United States Public Health Service. (Public Health Reports, 1932, xlvii, 601-613.)

During the fiscal year ending June 30, 1931, the average daily population of The National Leper Home at Carville, La., was 322. Sixty-three new patients were admitted, 3 absconded, of whom one returned within one month at his own expense, 9 patients who had absconded in previous years returned for hospitalization, 5 of them paying their own expenses. Nineteen patients were paroled. Of the 337 patients in the hospital on June 30, 1931, 178 were taking chaulmoogra oil

by mouth, the dosage varying from 5 to 125 drops three times a day. About one-third of the patients were taking chaulmoogra oil with benzocaine by intramuscular injection twice weekly, the average dose being 5 cc. Of the 49 patients who had been taking the intramuscular treatment for two years, 33 were markedly improved, 14 were moderately improved, and 2 were slightly improved. Of 131 patients who had taken treatment for over 12 months, 66 showed marked improvement, 50 showed moderate improvement, 8 showed slight improvement, and 7 were unchanged. Of the two groups, 34 were bacterioscopically negative. Forty-eight patients were treated with the ethyl esters of hydnocarpus. Intramuscular injections of the esters in doses of 2 or 3 cc. were given once a week and proved much less irritating than the esters of chaulmoogra oil. The beneficial results were about equal to those obtained with the ethyl esters of chaulmoogra oil. The sera of all new patients were examined by the Kolmer quantitative complement fixation method and Kahn precipitation test. Of the 110 examinations made by each method, 49 sera were negative by both Kolmer and Kahn methods, 24 were negative by Kolmer and positive by Kahn, 10 of which showed a 3 plus or higher reading by the Kahn method, and 6 were negative by Kahn and positive by Kolmer, all but 3 of which, however, showed a weakly positive reading by the Kolmer method.

The Present Status of BCG Vaccination. By S. A. PETROFF, Ph.D. (The New Engl. Jr. of Med., 1932, ccvi, 436-439.)

No problem in tuberculosis, since the famous controversy on the entity of bovine and human tuberculosis some twenty-five years ago, has created such a feverish discussion as the prophylactic immunization against tuberculosis known as BCG vaccination. From study of three different cultures of BCG, obtained at different times and from three different sources, the last directly from Professor Calmette, Petroff came to the conclusion that BCG was an organism of low virulence, producing tuberculous changes which had the tendency to heal. But with each of the three cultures, a small number of ani-

mals which had been under observation for about eighteen months developed progressive tuberculosis. The organism isolated from the lesions of these animals, when inoculated into healthy guinea pigs produced a progressive disease which could be transferred in a series of animals. Dissociation phenomena may be appealed to to explain the instability of the organisms and the resulting variation in virulence. The differentiation of human and bovine tubercle bacilli by animal inoculation is at present inadequate. Among the cultures obtained from human material, a large number cannot be classified as either human or bovine. As to the Lubeck disaster, Petroff does not believe that the vaccine used for the babies was contaminated with human type tubercle bacilli, but that reversion of the virulence had taken place. Petroff is strongly opposed to the use of a living virus as a vaccine against tuberculosis. An organism which is now nonvirulent may regain its virulence after passing through a suitable environment and in time may become a menace to the person who has been vaccinated.

Über Ulkuszunge [Ulcer Tongue] By PROF. DR. K. GLAESSNER (Arch. f. Verd.-Krankh., 1932, li, 68-73)

In patients with gastric or duodenal ulcer there is frequently found a characteristic change in the tongue consisting of solitary or multiple epithelial defects. These occur chiefly in the posterior segment of the tongue, either in the mid-line or anterior to the circumvallate papillae. They are frequently symmetrical but may be unilateral and exhibit a defect which lays bare the corium. They are round or oval, frequently elongated, are entirely superficial, non-painful and give the impression of superficial ulcers. In size they range from 2 to 8 mm. in diameter. Glaessner has seen these lesions in more than 50 cases. Their presence speaks for peptic ulcer, but their absence must not be taken as evidence against an ulcer diagnosis. Once present, the tongue lesions appear to remain as long as the gastric ulcer persists. With its healing they disappear. The author believes this to be a hitherto undescribed form of glossitis characteristic for peptic ulcer.

Reviews

A Diabetic's Own Cook Book By STELLA H. LYONS, with a foreword by LOGAN CLENDENING, M.D., F.A.C.P., xii + 94 pages. Alfred A. Knopf, New York City, 1932. Price, \$2.00.

Mrs. Lyons is a good cook—and also a diabetic. How often, when faced with the common "hospital" list of foods useful for this ailment, has the physician been told "I'd rather die than diet!" Certainly, in her little volume "A Diabetic's Own Cook-Book", Mrs. Lyons has taken the "die" out of "diet". And—blessed relief to the diabetic,—she has done it without entangling him in a mass of weighing-scales, measuring glasses and logarithm-like tables of figures. In fact, the only evidence of these bug-a-boos lies on the title page set up by the publisher. After a common-sense layman's talk to the layman, dealing with the principles of feeding necessary to diabetics, Mrs. Lyons plunges at once into her main task, food and how to cook and

serve it. It's good food, too, food which any non-diabetic could and would enjoy. Moreover, the recipes, practically, are criticism-proof from the technical viewpoint. These recipes should prove most helpful not only to diabetics but also to dietitians in institutions who have "worn out" their stock meal-lists and to physicians who wish to put "life" into the sober lists of "allowed" foods as set forth in standard books on dietetics. Not in the least in value is the wholesome, "good housewife" optimism which pervades Mrs. Lyons' brochure. Steffanson startled the professional North Pole chaser with his book entitled "The Friendly Arctic", Mrs. Lyons similarly has removed a host of horrors by her courage in being "friendly" toward diabetes and its demands of "eating to live".

FRANK SMITHIES, M.D., M.A.C.P.

Italian Medicine By ARTURO CASTIGLIONI, M.D., Professor of the History of Medi-

cine, Royal University of Padua, Italy. Translated by E. B. Krumpholtz, M.D., Professor of Pathology, University of Pennsylvania. vi + 134 pages. 11 illustrations. Paul B. Hoeber, Inc., New York City, 1932. Price, \$1.50.

Italian Medicine is the sixth member of the *Clio Medica* series. Like its predecessors it provides in readily portable form—in a coat pocket size, in fact—a readable survey of a limited field in medical history. It is intended to orient the reader in the special domain of the subject. The sponsors of the series are fortunate in securing an eminent Italian scholar of the History of Medicine as author. The translation is also excellent. It has a literary value of its own and is free from the idiom of the original. The reviewer questions the suitability of the subject for a *Clio Medica* volume. Would it not have been better to have subdivided the topic in order to permit fuller treatment? The author himself writes, "The history of Italian medicine is too vast and complex to be concentrated in a small volume. I have tried merely to outline its history in its high points from the time of the school of Salerno to the present day. It would not be possible even to name all the famous schools and illustrious physicians." The typography is good and the binding serviceable. In a modestly priced volume an excellent reference handbook to the more significant men and events in Italian Medicine is provided. If the subject proved too large for treatment in so small a compass, all the more does this book whet the appetite for a larger portion, and this is one of the aims of *Clio Medica*.

Female Sex Hormonology. A Review. By WILLIAM P. GRAVES, A.B., M.D., F.A.C.S., Professor of Gynecology at Harvard Medical School, Surgeon-in-Chief to the Free Hospital for Women and to the Parkway Hospital, Brookline, Massachusetts. 131 pages, 9 illustrations. W. B. Saunders Company, Philadelphia and London, 1931. Cloth, \$3.00.

This little book is in truth an interesting review of female sex hormonology. The author first deals with the very earliest work which proved the ovary to be a gland of internal secretion. He briefly reviews the

sex cycles in animals. After discussing the cycle in the ovary, he describes the uterine cycle and its correlation with that of the ovary. This relationship is clearly illustrated with diagrams. The author reminds the reader how closely the last phase of the endometrial change imitates an early decidual change, a fact of some importance. The animal experimental work is described which led to the isolation of the two ovarian hormones and the functions of these hormones, the finding of "folliculin" in various tissues of the female and even in the male and in plants. Later it was found that the corpus luteum also secretes a specific hormone, which prepares the uterus for the reception of the embryo. It has been proven that the secretion of the follicle and of the corpus luteum are antagonistic and are also synergistic. The author questions whether these two known hormones are simple or complex. The work leading to the development of the Ascheim-Zondek test, and the subsequent finding of at least two hormones of the anterior lobe of the hypophysis and their correlation with the ovarian hormones are fully presented. These investigations have led to new theories of menstruation, parturition and lactation. The author constantly emphasizes the rhythm of the sexual cycle in all its functions. The lack of success in organotherapy in the past he believes to be due largely to the use of extracts from the wrong organ. At the end of the book is a useful glossary and under the definition of "hormone" is a list of some of the proprietary hormone preparations, classified as to source. There is also an extensive bibliography. This book is stimulating and well worth reading.

Síndrome de Oclusión Coronaria [The Syndrome of Coronary Occlusion] By ANTONIO BATTRO, Médico Agregado del Hospital Nacional de Clínicas, Médico Inspector del Dispensario Público Nacional Antituberculoso de Belgrano, Adscripto a la Cátedra de Clínica Médica. 214 pages, 111 figures. Librería "El Arteneo", Buenos Aires, 1930.

This is an excellent monograph on occlusive disease of the coronary arterial system. The first 38 pages are given over to anatom-

ical considerations and are supplied with excellent illustrations, in part from Spalteholz and other sources, and in part original. The next section deals with the physiology of the coronary circulation, including the coronary vasomotor mechanism and the action of certain drugs. A brief discussion of etiologic factors is followed by a description of the clinical syndrome of myocardial infarction. In the remaining sections the following topics are presented: An experimental and clinical study of coronary occlusion by the electrocardiograph, the evolution of the syndrome, the pathological anatomy of coronary occlusion, the clinical forms of the syndrome, differential diagnosis, prognosis, and treatment. The bibliography contains 188 titles, and there is a table of contents in outline form.

Clinical Atlas of Blood Diseases. By A. PINNEY, M.D., M.R.C.P., Director of Pathological Department, The Cancer Hospital, London, Consulting Pathologist, Chelmsford Hospital, and STANLEY WYARD, M.D., M.R.C.P., Physician, The Cancer Hospital, London, and Princess Beatrice Hospital. Second edition. xvi + 105 pages. 38 illustrations of which 34 are in color. P. Blakiston's Son and Company, Inc., Philadelphia, 1932. Price, \$4.00 net.

This small book combines the functions of an hematological atlas and of a concise textbook upon the diseases of the blood. The necessity for a second edition within two years of the first is sufficient evidence that the work is supplying an actual need. The color plates, for the greater part, give the appearances of the various types of blood cells as stained by the Jenner-Giemsa method, at a magnification of 1,000 diameters. A brief, and therefore necessarily somewhat dogmatic, account of almost all hematological diseases is provided. The omission of any reference to ovalocytosis is noted, but sickle cell anemia has both a color plate and a discussion. A glossary of hematological terms, brief expositions of the Arneth and Schilling indices, 'family trees' of the various blood cells, and an all too brief appendix on the technic of blood examination are included. This book can be fully recommended for its purpose. The price is justified by the numerous figures in colors.

How's Your Blood Pressure? By CLARENCE L. ANDREWS, M.D., F.A.C.P., Attending Physician and Medical Chief at the Atlantic City Hospital. x + 225 pages. The Macmillan Company, New York City, 1931. Price, \$2.50.

This little book is written for "the victims of blood pressure psychology who live in constant fear of some impending calamity which may never occur." Couched in simple language intended to elucidate the subject of blood pressure for the laity, free use is made of homely similes to illustrate the physiology and anatomy of the circulation. The author takes up first in a general way the need for a circulatory system, then treats of some of the factors concerned with the maintenance of the blood pressure in health and disease. The general facts concerning blood pressure and its variations are accurately stated and no exception can properly be taken to the author's advice for the maintenance of a sound circulation. That faulty blood pressure is not a disease *per se*, is constantly kept before the reader. Perhaps, in an effort to state his thesis simply, the author has erred in the direction of excessive simplicity of style and in the presentation of facts already well known to intelligent laymen, but sound advice, sympathetically set forth, characterizes this thoroughly wholesome book.

Das Chlorophyll als Pharmakon [The Pharmacology of Chlorophyll]. By PROF. DR. EMIL BURGI. 84 pages, 28 graphs. 1932, George Thieme, Leipzig. Price, M. 6.40.

In this well-printed monograph various pharmacologic aspects of chlorophyll are considered in detail. Such are its part in the synthesis of hemoglobin and development of erythrocytes, its further effects upon the blood picture, its tonic effects upon the organism as a whole and upon certain organs and tissues, and its dosage and therapeutic availability. Two and one-half pages of bibliographic references to chlorophyll are appended.

Trust and Carl Schurz Foundation Later he will go to Vienna

Dr Elliott P Joslin (Fellow), Boston, Mass., was awarded the Kober Medal by the Association of American Physicians, at a meeting of the Association in Atlantic City on May 4. The medal was awarded to Dr Joslin because "for many years, he has been one of the world's leading authorities on diabetes mellitus. He has carried on important researches in this field. He has simplified and standardized treatment. He has been a great educator in the management of diabetes. He has trained doctor, nurse and patient in the use of his methods both individually and by group instruction. His textbook on diabetes, which has gone through four editions is a mainstay of both physician and medical student. His small manual is the bible of the diabetic patient. It is believed that his life work represents a type of sustained and scholarly performance for which Dr Kober would have been glad to see his prize awarded."

Dr Leonard G Rowntree (Fellow), Rochester, Minn., has been appointed Director of the Philadelphia Institute for Medical Research, which will open its doors next fall at the Philadelphia General Hospital, according to a statement issued recently by Dr Judson Daland (Fellow), Philadelphia, President of the Institute and one of its founders in 1922. Opening of the Institute will give Philadelphia, according to Dr Daland and his colleagues, a research organization with few rivals the world over. In addition to its own research work, the new Institute will hold itself ready to cooperate in medical research by collaboration or affiliation with any or all medical and allied institutions desirous of establishing such relationship. It will occupy a somewhat analogous position to that held by the Thorndike Institute of Boston. Dr Rowntree, the new Director, was graduated in medicine at the University of Western Ontario in 1905. Since that time he has held many posts of importance among which are the following: associate professor of medicine at Johns Hopkins University School of Medicine, chief of the department of medicine of the University of

Minnesota, member of the Air Service Medical Staff in France during the World War, senior medical consultant and director of Clinical Investigation of the Mayo Clinic.

The following Fellows of the College appear on the Medical Advisory Board of the Institute: Dr S Solis-Cohen, Dr Joseph C Doane, Dr D J McCarthy, and Dr Jefferson A Clark.

Dr E J G Beardsley (Fellow), Philadelphia, addressed the Woman's Auxiliary of the Burlington County Medical Society at the Community House, Moorestown, N J., on Monday, March 21. His subject was "Never Changing Truths Concerning Medicine and Life."

Dr Ralph deBallard Clarke (Fellow), Meriden, Conn., took part in a symposium on collapse therapy at the Danbury (Conn) Hospital on February 9, 1932. At this time he addressed members of the Danbury Medical Society and physicians from surrounding towns on the subject "Phrenicectomy and Artificial Pneumothorax in Tuberculosis of Children", illustrating his talk with X-ray films of cases under compression-therapy among children at Undercliff, the Connecticut State Childhood Tuberculosis Sanatorium at Meriden, Conn.

Dr Roland N Klemmer (Fellow), Lancaster, Pa., was elected Medical Director of the Lancaster County Hospital, Lancaster Pa., at a recent meeting of the newly organized Staff.

Dr Albert E Russell (Fellow), Washington, D C., was detailed by the Public Health Service to give an address on "Silicosis and Tuberculosis" at a joint meeting of the Trudeau Club and the St Louis, Mo., Medical Society on April 5, 1932.

Dr Lewis J Moorman (Fellow), Oklahoma City, is President of the Southern Medical Association.

Dr Charles Hartwell Cocke (Fellow) Asheville, N C., Governor for North Carolina, is Second Vice-President of the same body.

An Experimental Basis for Intravenous Vaccine Therapy in Chronic Arthritis With a Summary of Results Obtained in Patients*†

By B J CLAWSON, M D, and M WETHERBY, M D, *Minneapolis, Minn*

THE factors considered as a basis for intravenous streptococcic vaccination reported in this paper are (1) etiology and (2) a method of vaccination which will not produce hypersensitiveness (allergy) and will desensitize patients already hypersensitive and will produce a high degree of protective immunity

ETIOLOGY

The belief that most cases of chronic arthritis are infectious in origin is quite generally accepted. The exact infectious agent and the manner and form in which the agent finds its way into the joints are not so generally agreed upon. Some people believe that there is a direct infection of the joint by the living organisms. Others look upon the lesions in the joint as a response to inanimate parts of the infectious agent which lives in some remote focus. The etiology of chronic arthritis has been studied from the bacteriological, immunological, and pathological standpoints

Presented at the San Francisco meeting of the American College of Physicians, April 6, 1932

From the Departments of Pathology and Medicine of the University of Minnesota

Bacteriology Streptococci have been recovered from chronic arthritis in higher percentages and by a greater number of workers than any other organism. The materials cultured have been the blood, the joint fluid and tissues, the lymphnodes, and the subcutaneous nodules. The number of cases and the sources of the materials cultured with the percentage of positive streptococcic cultures obtained by many workers are given in tables 1, 2, 3, 4, and 5. The average percentage of positive streptococcic cultures obtained are as follows: blood, 35 per cent, joint fluids, 35 per cent, joint tissues, 44 per cent, lymphnodes, 61 per cent, and subcutaneous nodules, 72 per cent. Twelve hundred and ninety-seven cultures have been reported. Five hundred and twenty (40 per cent) were positive for streptococci (table 6). Recent workers have raised these percentages very decidedly.

The kind of streptococci recovered has, in the main, been *Streptococcus viridans*. Beta hemolytic streptococci have been found in a small percentage of the cases. Cecil, Nicholls and Stainsby⁴ most frequently recovered atypical hemolytic streptococci.

The strains studied by us have in most cases cross agglutinated with one

another and equally well with strains of acute rheumatic origin. The strains of streptococci from both acute rheumatic fever and chronic arthritis have in our experience tended to fall into a fairly well defined group which generally grew poorly when first isolated and produced a faint green discoloration on the blood agar plate when incubated at 37°C for 24 hours. These organisms do not seem to represent a specific strain.

Immunological Reactions The two immunological reactions studied in patients with chronic arthritis were (1) hypersensitiveness (allergy) as indicated by the skin test and (2) streptococcic agglutination.

Birkhaug¹⁸ showed by skin tests that patients having chronic arthritis

were hypersensitive to streptococcic protein in a higher percentage than normal persons. We obtained similar results in a study of 127 cases of chronic arthritis and 107 normal persons (table 7).

Nicholls and Stainsby¹⁹ found that the serums of patients with chronic arthritis agglutinated streptococci in higher dilutions than the serums from normal persons. We tested the serums from 81 normal individuals and from 60 patients with chronic arthritis (table 8). The strain of streptococcus used had been isolated from a case of chronic arthritis. The greatest percentage of the serums of the normal people showed agglutination in the dilution of 1:400 and the greatest number of the chronic arthritics in the dilu-

tion of 1:800. Only 28 per cent of the normal persons showed agglutination above 1:400. The per cent above 1:400 in the chronic arthritic patients was 60.

The higher percentage of positive skin tests and streptococcic agglutination titers in patients with chronic arthritis suggests a possible etiological relationship of the streptococci to chronic arthritis.

Pathological Findings. The cellular reactions in the joint capsules and membranes as described by Nichols and Richardson,²⁰ Margolis and Dorsey,¹⁴ and others were polyblastic in character and decidedly resembled those described by Swift²¹ in joint lesions in acute rheumatic fever.

We observed subcutaneous nodules in 30 per cent of a series of 300 cases of chronic arthritis. We found the cellular reaction in these nodules, as did Coates and Coombs,²² to be similar to the reactions in subcutaneous nodules and heart valves in acute rheumatic fever and in heart valves in subacute bacterial endocarditis. The reaction was also similar to that in subcutaneous nodules produced experimentally in rabbits by injecting streptococci.

The bacteriological, immunological, and pathological findings described above tend to support a causal relation between streptococci and chronic arthritis.

METHOD OF VACCINATION

An effort was made to see what could be done by vaccination toward protecting patients having chronic arthritis. Animal experiments were carried on toward developing an efficient method of vaccination which

would give the highest degree of immunity against streptococci.

The things necessary in a vaccine for chronic arthritis are (1) not to make the patient hypersensitive to the protein in the vaccine, (2) to desensitize the patients who are already hypersensitive, and (3) to bring about a high degree of protective immunity.

The following experiments in rabbits showed that the intravenous injections of streptococci met the three above requirements while the subcutaneous injections did not.

Hypersensitiveness (Allergy). The degree of tissue response as an indicator of hypersensitiveness is shown in table 9. The tissue response in terms of percentage was compared in normal, hypersensitive, and immune rabbits. The hypersensitiveness was produced by injecting animals subcutaneously in one area with a mixture of agar and streptococci. The immune state was brought about by repeated intravenous injections of streptococci. Each of the animals in the three groups was then injected subcutaneously in each of ten places on the back with a known number of streptococci. All animals were killed five days later and the number and the size of the nodules at the sites of the small multiple subcutaneous injections were determined. The tissue response (cellular reaction) in these nodules was similar to the type of reaction found in lesions in chronic arthritis. The tissue response in the normal animals was 3.2 per cent, in the hypersensitive animals, 88 per cent, and in the immune animals, 1.1 per cent. The average streptococcic agglutination titer in the hypersensitive animals was 1:3200, and in the immune animals,

1 200,000 These experiments confirmed the findings of Swift²³ in that animals injected subcutaneously were made hypersensitive while the animals injected intravenously were not The subcutaneous method of giving a vaccine will not desensitize the hypersensitive animals, for hypersensitiveness is produced and maintained by subcutaneous injections

Desensitization Ten animals were made hypersensitive as described above and later vaccinated intravenously with *Streptococcus viridans* The degree of tissue response, indicative of hypersensitiveness in these ten vaccinated animals, was compared with that in hypersensitive animals which had not been vaccinated (table 10) The non-vaccinated hypersensitive animals showed 88 per cent of tissue response The hypersensitive animals which had been vaccinated intravenously gave a tissue response of 52 per cent The average agglutination titer in the non-vaccinated hypersensitive animals was 1 3200, and in the vaccinated hypersensitive animals, 1 50,000 The hypersensi-

tive animals were desensitized by the intravenous method of vaccination The intravenous method met the two necessary requirements in not bringing about a state of hypersensitiveness (table 9) and in desensitizing animals which were already hypersensitive (table 10). As far as hypersensitiveness is concerned the intravenous method of vaccination rather than the subcutaneous method should be used

Protective Immunity It was seen in the preceding experiments that the streptococcic agglutination titers were decidedly higher in animals injected intravenously than in animals injected subcutaneously To test the protective merits of the subcutaneous and intravenous methods of injecting a streptococcic vaccine two groups of animals were selected Group 1 was vaccinated subcutaneously at five weekly intervals with one billion killed streptococci Group 2 was vaccinated intravenously at the same periods with the same doses The streptococcic agglutination titers of the two groups were then determined (table 11) The animals vac-

	1 30	1 3200	1 360,000

culated subcutaneously had titers ranging from 1 1600 to 1 6400. The animals vaccinated intravenously had titers of from 1 200,000 to 1 400,000. If the height of the agglutination titer can be relied upon as an indicator of the degree of immunity, then it is obvious that a much higher degree of protection can be produced against streptococci by intravenous injections than by subcutaneous injections of a vaccine.

The evidence of a correlation between the height of an agglutination titer and protection was shown by comparing the rate at which streptococci were killed in normal animals and in animals which had a high agglutination titer and by comparing the bactericidal power of the blood of vaccinated and

non-vaccinated chronic arthritic patients.

Normal rabbits and rabbits highly immune to streptococci were injected intravenously with 50 million live streptococci. In 15 minutes 1 c.c. of blood was taken from the heart of each animal and plated on agar. In two hours the animals were killed and a gram of liver from each animal was ground in a mortar and plated in dilutions on agar. It was found in the series of ten rabbits of each group that the rate of disappearance of the streptococci from the blood in 15 minutes was three times greater in the immune than in the normal animals (table 12). The rate at which the streptococci were killed in the livers of the animals in

two hours was 33 times greater in the immune animals (table 13). The streptococcic agglutination titers averaged 1:45 in the normal animals and 1:170,000 in the immune animals.

It was found by using the method of Sutliff and Rhoades²⁴ for determining the bactericidal power of whole blood that the whole blood of vaccinated chronic arthritic patients with an agglutination titer of 1:6400 or more had a much greater bactericidal power for

streptococcic agglutination than the blood of non-vaccinated patients with an average streptococcic agglutination titer of 1:200 (table 14).

Since the agglutination titer rises decidedly higher by the intravenous method of vaccination than by the subcutaneous method and since the above experiments in animals and patients showed a correlation between an elevated agglutination titer and desensitization and protective immunity, the

intravenous method of administering a vaccine would seem to be the one of choice

Type or Species Specificity in Desensitization and Protective Immunity If desensitization and immunity should be type (strain) specific, then it would seem that autogenous vaccines should probably be used in most cases. If, on the other hand, these two phenomena should be only species (group) specific, then a stock streptococcic vaccine would in most cases likely be sufficient. This is an important consideration, for it would be impracticable to use autogenous vaccine in treating chronic arth-

ritis in most cases. Experiments were carried on with animals to determine the relation of acquired desensitization and immunity to type and species specificity.

Animals made hypersensitive to *Streptococcus viridans* of acute rheumatic origin were vaccinated intravenously with *Streptococcus hemolyticus* from a case of puerperal sepsis. The degree of tissue response to *Streptococcus viridans* indicative of hypersensitivity was determined and compared with non-vaccinated animals which had been made hypersensitive to *Streptococcus viridans* (table 15). The

10	9	0.2
	88 per cent	0.4 per cent

response in the non-vaccinated animals was 88 per cent and in the animals vaccinated with *Streptococcus hemolyticus*, 0.4 per cent. The desensitization did not seem to be type specific.

In a series of ten animals each animal was immunized with a different strain of streptococcus of chronic arthritic origin and later each of the animals was injected with 50 million organisms of another strain of streptococcus. The rapidity with which this organism disappeared from the blood (tested in 15 minutes) and from the liver (tested in two hours) was much greater than in normal animals. These experiments suggested that protective immunity also was not type specific.

Non-specific Protein Therapy (B typhosus) in Streptococcic Infections
Intravenous injections of *B. typhosus* are commonly used in treating chronic arthritis. Experiments were performed in animals to see what relation intravenous injections of *B. typhosus* bore to the desensitization of animals hypersensitive to *Streptococcus viridans*

and to the protection of animals against *Streptococcus viridans*.

Animals were made hypersensitive to *Streptococcus viridans* and vaccinated intravenously with *B. typhosus* (table 16). The tissue response to *Streptococcus viridans* in these animals was compared with the response in non-vaccinated hypersensitive animals. The response in the non-vaccinated animals was 88 per cent and in the animals vaccinated with *B. typhosus*, 82 per cent, as compared with 0.7 per cent in the hypersensitive animals vaccinated with streptococci. It was concluded that desensitization to streptococci was not brought about by a non-specific protein reaction.

Animals vaccinated intravenously with *B. typhosus* developed a high agglutination titer to *B. typhosus* but the titer to *Streptococcus viridans* was raised but slightly. When these animals were injected intravenously with 50 million streptococci it was found that the rate at which the streptococci disappeared from the blood was even less

than in normal animals (table 17) Protection against streptococci was not brought about by intravenous vaccination with *B typhosus*

It can be concluded on fairly good experimental grounds that streptococcic desensitization and protection are species specific but not type specific and that they are not brought about by a non-specific protein reaction

The above findings and experiments supply the following conclusions as a basis for intravenous streptococcic vaccination in chronic arthritis

1 Non-specific chronic arthritis in most cases appears to be due to a

streptococcic infection (not a specific strain)

2 Subcutaneous injections of a streptococcic vaccine do not desensitize the hypersensitive individual but tend to increase the hypersensitive state

3 The subcutaneous method develops only a slight degree of protection

4 The intravenous method of giving a streptococcic vaccine desensitizes the hypersensitive patient, does not develop hypersensitiveness, and does cause a high degree of protective immunity to be developed

5 Neither the desensitizing nor the protective phenomena are type specific but they appear to be species specific. They are not of the nature of a non-specific protein reaction.

These conclusions were the basis of the experiments in the intravenous vaccine therapy in 301 cases of chronic arthritis reported in this paper.

SUMMARY OF RESULTS

Three hundred and one cases of chronic arthritis have received five or more intravenous injections at weekly intervals. The organism used in the vaccine was from a case of acute rheumatic fever and had been cultured for nine years, was of low virulence, did not agglutinate spontaneously, and was safe for intravenous injections. Cross agglutination occurred in high dilutions (1:50,000) with many other strains of both acute rheumatic and chronic arthritic origins.

Dose The initial dose was 100 million organisms. This was increased by 100 million organisms at weekly injections. As a rule not more than eight to ten injections were given.

Reactions Slight reactions with temperature and chills occurred in

about 50 per cent of the cases. The degree of reaction seemed to have no relation to the clinical improvement.

Number of Injections Necessary for Clinical Improvement Nearly two-thirds of the patients experiencing improvement did so after five injections, nine-tenths did so after seven injections. There were very few cases in which improvement took place, if it had not occurred with eight to ten injections (table 18).

Agglutination Titers and Vaccine Therapy The greatest percentage of untreated patients showed an agglutination titer of 1:200 with the strain of streptococcus used in the vaccine. The intravenous vaccine therapy stimulated a definite rise in the agglutination titers in the serums of most of the patients. Clinical improvement occurred most frequently when the titer was 1:6400 or more (table 19). The height of the streptococcal agglutination titer seemed to be a reliable indicator in most instances of the protection possessed by the patient against streptococci.

Results Determination of clinical improvement was based on three criteria: (1) decrease in pain, (2) decrease in joint swelling, and (3) increase in joint movement.

No improvement	49	16.3

Excluding the 19 questionable cases the results for the different criteria for improvement are tabulated as follows:

Definite clinical improvement was observed in 80 per cent of the cases treated.

DISCUSSION

An experimental basis for intravenous streptococcic vaccination in chronic arthritis and the results of such vaccination in 301 patients are discussed in this paper.

Streptococcic vaccination seems to be indicated because chronic arthritis appears to be due to a streptococcic infection. The things to be considered as evidence for the etiology of chronic arthritis are: (1) Streptococci have been recovered from the blood, joints, lymphnodes, and subcutaneous nodules from a relatively high percentage of cases of chronic arthritis. (2) A high percentage of patients having chronic arthritis are found by the skin test to

be hypersensitive (allergic) to streptococci. (3) The streptococcic agglutination titer is higher in patients with chronic arthritis than in normal persons. (4) The cellular reactions in lesions in chronic arthritis are similar to those of known origin, such as acute rheumatic fever and subacute bacterial endocarditis.

The intravenous method of administering the vaccine is indicated rather than the subcutaneous method for the following reasons: (1) The intravenous method does not produce hypersensitiveness, as does the subcutaneous method, but desensitizes the patient who is already hypersensitive to streptococcic protein. (2) Subcutaneous injections of streptococci produce only a slight degree of protection, while the intravenous method results in a high resistance.

An autogenous vaccine does not seem to be necessary since both the desensitizing and protective phenomena seem

TABLE 21

	NUMBER OF CASES	PER CENT

Unchanged	37	18.8
3. Joint motion		
Increased motion	206	84.7
Unchanged	37	15.3

to be species (group) specific rather than type (strain) specific

The use of intravenous injections of *B typhosus* in treating chronic arthritis is contraindicated, since such injections do not desensitize patients hypersensitive to streptococci and do not cause the development of a protective immunity in the patient against streptococci

Intravenous injections of streptococci can safely be administered to patients. Such injections in our series of 301 patients have resulted in definite clinical improvement in about 80 per cent of the cases

The streptococcic agglutination titer of the serums of these patients appears to be a reliable indicator in most cases of the protection possessed by the patient against streptococci.

These experiments have not been in effect long enough to draw definite conclusions concerning the duration of the clinical improvement. In a few cases the clinical improvement and a high agglutination titer have been sustained for as long as eight months

CONCLUSIONS

1 Intravenous streptococcic vaccination seems to meet the demand of a method of vaccination for chronic arthritis in not increasing hypersensitivity, in desensitizing the already hypersensitive individual, and in producing a high protective immunity against streptococci.

2 The subcutaneous method seems to be contraindicated, since it tends to increase hypersensitivity, does not bring about a state of desensitization, and produces only a low degree of protection

3 The intravenous injection of *B typhosus* in treating chronic arthritis would seem to be contraindicated

4 About 80 per cent of the patients with chronic arthritis who received five or more intravenous injections of a streptococcic vaccine showed definite clinical improvement

5 The results obtained in treating patients with chronic arthritis by intravenous streptococcic vaccination seem to justify the further study of such treatment.

Hypertension and Diabetes*†

By HENRY J. JOHN, M.D., F.A.C.P., *Cleveland, Ohio*

THAT the blood pressure rises as a result of increase in weight in non-diabetic individuals has been shown by various authors^{3, 11, 15, 16, 17, 18, 11}. One striking example of this relationship is shown in the data reported by Hartman and Ghrist¹⁰ of the Mayo Clinic, who in 1922 analyzed a series of 2,042 consecutive cases of this type which were seen there. The males and females were practically equally divided. The summary of this study may be expressed by the following

Blood pressure in the total number of cases of underweight (male)	125 1
Blood pressure in the total number of cases of overweight (male)	141 2
	(12 38 per cent)
Blood pressure in the total number of cases of underweight (female)	127 2
Blood pressure in the total number of cases of overweight (female)	142 2
	(11 81 per cent)

Observations by Terry¹⁷ and Rose¹⁸ showed that in patients presenting hypertension with obesity, merely the reduction of their weight brought about also a decrease in their blood pressure. Therefore, obesity may be looked upon as one of the etiological factors in the production of hypertension in non-diabetics.

If overweight is an important factor in hypertension how does the group of patients afflicted with diabetes stand

in relation to overweight? Such information should give us one of the clues to a further analysis of this question. In 1930, I¹⁹ published a study of a series of 528 cases of diabetes studied from the standpoint of weight at the time I saw them for the first time or at any time of their life. The following data were obtained from this study.

Normal weight (below normal and up to plus 10 per cent above normal) in 24 per cent
Overweight (above 10 per cent) in 76 per cent

It is evident then, that overweight is a definite factor in diabetes.¹⁹ The distribution of overweight in the various decades compared with normal weight is shown in chart I.

The weight factor is of course only one of the links in the chain of hypertension, but it is a significant one. The immediate causes of hypertension are still sufficiently uncertain to warrant a new hypothesis, for many causative factors have been suggested. For a brief review we may consider the following possible causes of hypertension: (1) arteriosclerosis in diabetes,^{24, 26, 27} (2) increase in cholesterol

*Received for publication, September 10, 1931

†From The Cleveland Clinic, Cleveland, Ohio

CHART I The distribution of overweight pounds in the author's series of 528 cases diabetes arranged according to decades

circulating blood,^{24, 25, 29, 30, 34, 35} (3) blood peptides,²⁸ (4) anemia brain,^{30, 38, 39, 40} (5) hyperglycemia,^{31, 32, 34, 35, 37} (6) insulin administration,³³ (7) hyperthyroidism, (8) ney disease,³⁶ (9) heredity,^{42, 43} (10)

In this same series Adams points out that 162 per cent of the male diabetics had a systolic blood pressure of more than 150 mm as against 24 per cent of Exton's normal males, 267 per cent of the female diabetics had a systolic pressure of more than 150 mm as against 43 per cent of Exton's normal females. This is offset by the fact that in Adams' cases 156 per cent of male diabetics had a blood pressure lower than 110 mm as against 25 per cent of Exton's normal men, and 19 per cent of diabetic women had a systolic pressure of less than 110 mm as against 81 per cent of Exton's normal women. The apparent contradiction, Adams says, may be explained by the wide "scatter" of the blood pressure readings in diabetic patients as compared with the narrow scatter of blood pressure readings of normal persons.

The summary of Adams' study is shown in charts II and III. Chart II shows the blood pressure in all cases of diabetes as compared with that in a series of normals. Chart III shows the blood pressure in cases in which only diabetic patients who are free from

nephritis, arteriosclerosis and hyperthyroidism, are shown together with the normal series. He concludes that there is no appreciable increase of blood pressure in the diabetics over that of non-diabetics.

The range of opinion as to whether blood pressure is increased in the presence of diabetes can be noted from table I, in which I have tried to summarize the opinions of various authors on the subject. The consensus of opinion would seem to indicate that the blood pressure is increased in the presence of diabetes

My own studies comprise observations on 1,828 cases of diabetes mellitus. Of this group 1,385 cases are of diabetes mellitus and 443 are cases of diabetes mellitus associated with hyperthyroidism. Observations on blood pressures in diabetes, arranged according to decades, according to distribution between male and female are summarized in table 2. Throughout this study I have divided these observations arbitrarily into two groups. (1) cases in which the blood pressure has not exceeded 140 mm and (2) those in which the blood pressure is above 140

CHART II A comparison of the blood pressure of diabetic patients with the normal blood pressure (Adams⁵)

mm Details in regard to each group are given in each descriptive chart or table. It will be noted that the males and females were equally divided. Of the entire group, 54.3 per cent presented a blood pressure under 140 mm and 45.7 per cent had a blood pressure above 140. When we compare these data with the observations on non-diabetics furnished by Wiechmann⁴ as I have done in table 3, it will be seen in decades below and including the fourth the blood pressure is virtually the same in non-diabetics as it is in diabetics, while above this age the incidence of high blood pressure is greater in diabetics.

In order to further analyze the incidence of hypertension in non-diabetics I grouped a series of 11,840 cases from data furnished by Weitz, Gellman, Soller, Keith et al, Riseman and Weiss, Frost, Dublin, Fisk-Kopf, and Rogers-Hunter. The results of this analysis are presented in chart IV. It will be noted that the considerable increase in the incidence of hypertension begins with the fourth decade, and is greatest in the sixth decade after which it again declines.

Chart V shows a series of observations on my own cases in which the variation of blood pressure in various diseases is noted. A summary of the

results of observations of cases of diabetes associated with hyperthyroidism (as shown in table 4), is given below in comparison with the results of observations on cases of diabetes. It will be noted that there is a definite increase in the incidence of hypertension in the latter, and also that three-fourths of these patients are females.

A study of these two relationships analyzed from a somewhat different angle, namely, that of dividing each of these groups into cases up to 30 years of age and above this age, as shown in table 5, shows that in the group of

young diabetics hypertension is present in only nine per cent as contrasted with an incidence of hypertension in 42 per cent of cases of diabetes with hyperthyroidism. In diabetes, then, increase in blood pressure begins later in life, whereas if diabetes is complicated with hyperthyroidism such a rise occurs early in more than 50 per cent of cases.

Kramer,¹¹ who analyzed 500 cases of diabetes and compared these with non-diabetics, found that 38 per cent have hypertension, that is, a blood pressure above 150 mm.

	MALE PER CENT	FEMALE PER CENT	BLOOD PRESSURE BELOW 140 MM PER CENT	BLOOD PRESSURE ABOVE 140 MM PER CENT

THE RELATION OF HYPERGLYCEMIA TO HYPERTENSION

In 1910 Neubauer⁷⁶ noted the occurrence of hypertension associated with hyperglycemia and offered the theory that the excessive activity of the suprarenals might be the underlying factor. The question naturally arises—why should there be an excessive activity of the adrenals in old age? Even granting that the activity of the islands is lessened, due to arteriosclerosis or at any rate to a diminished blood supply, or to any other cause which might alter a normal activity of the adrenals thus bringing about hyperglycemia—yet the idea of an increase in the activity of the adrenal glands in old age does not seem logical. O'Hare⁷⁰ also noted the fact that there is a decline in tolerance for carbohydrates in *certain* examples of high blood pressure. He wrote "certain examples"—which indicates a general observation. Were the increase in blood pressure, *per se*, the only factor then we should find a decrease in tolerance for carbohydrates in all cases of progressively increasing blood pressure. He offered the explanation that sclerosis of the arteries of the pancreas might be the pathologic background for this condition. He

thinks that these cases are potential diabetic cases and need observation. On the other hand, Pearce and Keith⁷⁷ suggested that because a diseased kidney is unable to utilize the ordinary amount of sugar brought to it by the blood, a diminished sugar consumption results, together with increased accumulation of this substance in the blood stream. When one considers the total weight of the kidneys in relation to the weight of the rest of the body, it hardly seems possible that this would be the answer. Furthermore, when I think of the hun-

CHART V Chart showing the percentages of the cases in which the blood pressure was above 140 mm among the various groups classified according to affection (John)

TABLE 5

Study of Hypertension in Diabetes and Diabetes with Hyperthyroidism, the Cases Being Divided into Two Age Groups Those up to 30 and Those above 30 years of Age (John)

		DIABETES		DIABETES AND HYPERTHYROIDISM

	Above 140	621	49	258	65

dreds of renal conditions ranging from the mildest to the most severe, with but little kidney substance left functioning these patients meanwhile presenting repeatedly a normal blood sugar level, I feel quite strongly that diseased kidneys alone will not cause an appreciable rise in blood sugar. Meyers and Killian⁷³ noted an increase in the diastatic activity of the blood in examples of nephritis and expressed the idea that this might account for the hyperglycemia often noted in such cases. Harle,³⁶ in a study of a series of cases of hypertension, failed to discover any exact parallelism in the curves of blood pressure and blood sugar. He concluded that hypertension and hyperglycemia are not the common results of increased activity of the chromaffin system. Botti¹⁰³ stated that in the presence of hypertension the blood sugar is increased and the sugar tolerance lessened. Kylin⁸ has also described the association of lowered carbohydrate tolerance with hypertension. Herrick⁷¹ was led to believe from his personal observations that the occurrence of high blood pressure and increased concentration of glucose in the blood is present in a definite group of cases characterized by four cardinal symptoms: hypertension, hyperglycemia, obesity and arteriosclerosis. Mohler⁷² studied 46 patients varying in age from 30 years to 70 years with glycosuria and a blood pressure of 150 or more. Forty-five of the 46 patients ranged from 1 to 60 per cent overweight at the time of the observation, 36 of these weighing more than 200 pounds at some period of life. In 16 of these 36 patients, diabetes had developed. Mohler³ concluded that obesity frequently is a factor in the development

of sclerotic changes in the body which are capable of producing an increase in the blood pressure and a diminished ability of the body cells to utilize carbohydrate. Interesting are the studies of Hoppe-Seyler⁸⁴ and Herxheimer⁸⁵ who pointed out that in cases in which arteriosclerosis of the kidneys and hypertension are present, diabetes begins through an analogous arteriosclerosis of the pancreas. To this observation Wiechmann⁹⁸ added that a certain natural weakness of the pancreas may be a causative factor.

Tachau⁷⁴ and Harle³⁶ both found blood sugar values in nephritis with hypertension at the upper limits of the normal. In hypertension without clinically recognizable renal changes or other complications they found not only high blood sugar values but often definite hyperglycemia. Hitzengerber and Richter-Quittner²² found hyperglycemia present in all cases of vascular hypertension. Frank,⁸⁹ Billigheimer,⁸⁸ Kahler,⁸⁷ Petró,⁸⁸ Peiser,⁸⁹ Voegelin,⁹⁰ always found normal blood sugar values in hypertension or at least values that lie at the upper limits of normal.

In table 6 I have summarized the average blood sugar values given by seven different authors, these all fall within normal levels. In table 7 I have summarized further the conclusions of all the authors cited in this section on the relation of hypertension to hyperglycemia. Archer,² who studied a series of 20 typical cases of arthritis of the menopause, found in 70 per cent a diminished sugar tolerance in contrast to only 15 per cent in a parallel series of infectious cases. Of these 70 per cent of diminished sugar tolerance, 71 per cent had an associated hypertension or obesity or both.

Table 8 presents the summary of my own observations of 50 uncomplicated cases of hypertension, based on glucose tolerance tests, and classified according to decades. It will be seen that in the earlier decades the incidence of diabetic curves is zero, whereas in the fifth decade and up the diabetic incidence rises rapidly. This fact is also demonstrated in chart VI which shows

the rapidly increasing incidence with advanced years. This observation is in line with the pathological observations of Herxheimer,⁸⁵ Fahr,⁹⁷ Aschoff,⁹⁸ Seyfarth,⁹⁹ and others who have shown that in hypertension, it is not only the renal arterioles which are affected first and most but the pancreas also shows changes of arteriosclerosis when the arterioles of the rest of the body

are not affected with any regularity Herxheimer pointed out that in cases in which arteriosclerosis of the kidneys and high blood pressure are present, the pancreatic blood vessel changes and the resultant changes in the islands are secondary Fraenkel¹⁰⁰ stated "These changes [pancreas, especially the cells of the islands] will be found in such boundaries as the various pathological changes of the blood vessels, from the beginning of the spasm, then through the angioneurosis on up to arteriosclerosis" Wiechmann⁹⁹ clearly stated

"Just as nephrocirrhosis arteriosclerotica can be the cause for increased blood pressure, so can the cirrhosis arteriosclerotica of the pancreas (Herxheimer) be the cause for the changes of the carbohydrate metabolism We must also note that often we are dealing only with functional changes which lead to similar clinical results as morphological changes Just as the high blood pressure can be but functional, so also do we find functional changes in the blood vessels of the pancreas which lead to hyperglycemia

and other changes in the carbohydrate metabolism ”

In my series of 50 cases of hypertension, glycosuria was present in 18 cases or 36 per cent (See table 9) Glycosuria was present six times in the presence of normal glucose tolerance curves (39 per cent), and it was absent sixteen times in diabetic curves (55 per cent) This leads us to the evaluation of the renal threshold which can be estimated fairly closely from a

ades Also one finds in cases of hypertension changes in blood sugar which are characteristic of diabetes mellitus The type of hypertension is the same in both and whether we are dealing with a functional hypertension or an anatomic hypertension the blood sugar pictures in both are similar

Many of the workers in this field look upon these changes in a large number of cases of hypertension as a latent diabetes,^{4, 85, 91 97, 98, 99} a predi-

TABLE 9
Glycosuria in Fifty Cases of Hypertension (John)

GLUCOSE TOLERANCE CURVE	GLYCOSURIA	PER CENT	NO GLYCOSURIA	PER CENT

	NO CASES	DIABETIC PER CENT	NON-DIABETIC PER CENT
Glycosuria	19	66	33
No Glycosuria	31	52	48

glucose tolerance test Table 10 shows that 47 per cent of these cases have a renal threshold above 180, which is high In my previous publication¹⁰¹ the average renal threshold for hypertension cases was also high, namely 165 (The average ranges were from 110 to 216)

TABLE 10 Renal Threshold in Hypertension (John)	
Below 140 mg /100 c c	23%
141 to 180 mg /100 c c	30%
181 to 200 mg /100 c c	33%
201 to 250 mg /100 c c	14%

From the previous consideration, then, it seems that there is a close connection between hypertension and hyperglycemia which in turn means diabetes either functional or anatomic Hypertension occurs more frequently in diabetics, especially in the later dec-

abetic stage A prediabetic stage does not necessarily come to the foreground and develop into a full fledged diabetes I have various groups of cases of latent diabetes and I keep them in this stage merely by a slight regulation of their diet, by a close observation of their weight, and by seeing that these patients get plenty of exercise There are also many observations of the opposite nature, namely—a prediabetic stage—a disregard of any diet—the development of obesity—diabetes This is a natural sequence in the evolution of diabetes in such a group Many of these cases of hypertension also die early which is another factor in eliminating a certain number of diabetics from our records

THE RELATION OF OVERWEIGHT AND UNDERWEIGHT TO BLOOD PRESSURE IN DIABETES MELLITUS AND DIABETES WITH HYPERTHYROIDISM

This study is based on observations of a total of 1,051 cases. Of these, 614 were cases of diabetes mellitus (292 male and 322 female) and 186 were cases of diabetes with hyperthyroidism (46 male and 140 female). A brief summary of the rise of blood pressure incidence reported by various authors can be gleaned from table 11. Tables 12 and 13 show a detailed analysis of these two groups of cases which I am reporting classified according to per cent of overweight, the increase in blood pressure and the distribution of male and female cases. Table 14 presents a similar analysis of the cases of underweight (in this group are included normal weights, up to plus 10 per cent above normal, and all cases below normal), cases of diabetes and cases of diabetes with hyperthyroidism. The data offered in table 12 are graphically expressed in chart VII in which it is clearly shown that in 50 per cent

of the cases of diabetes the blood pressure is above 140, and in 50 per cent the blood pressure is below 140. With increase in weight there is a decided increase in blood pressure. The data offered in table 13 (Diabetes and Hyperthyroidism) are graphically expressed in chart VIII. Here we find that in 66 per cent of these cases the blood pressure is above 140 and in only 34 per cent is the blood pressure below 140. Here we do not find the orderly sequence of increase in blood pressure with increase of weight, for other factors in addition to overweight enter into this picture.

Table 15 presents a detailed comparative analysis of blood pressure studies in overweight and underweight. These data are graphically expressed in chart IX which shows the increasing incidence of high blood pressure in per cent in overweight diabetics and a similar, although not as marked, increase in the incidence of high blood pressure in the presence of diabetes associated with hyperthyroidism.

Chart X presents a general summary

DIABETES

CHART VII The relation of per cent of overweight to rise in blood pressure in diabetes

of the relationship of overweight and underweight to hypertension, that is, a blood pressure below and above 140 mm in diabetes and in diabetes with hyperthyroidism. In both conditions there is a definite increase in the incidence of hypertension in cases presenting overweight, and a definite decrease in the incidence of hypertension, which is most marked in uncomplicated diabetes, in cases of normal weight or underweight.

SUMMARY

1 Blood pressure in non-diabetics rises proportionately higher in the case of obese individuals than in those of normal weight (approximately 12 per cent increase)

2 Reduction in weight in non-diabetics brings about reduction in blood pressure

3 The consensus of opinion of various authors is that the blood pressure is higher in diabetics than in normal

CHART VIII The relation of per cent of overweight to blood pressure in diabetes and hyperthyroidism

CHART IX The comparative relationship of overweight, underweight, to the blood pressure incidence in diabetes and diabetes with hyperthyroidism

CHART X A summary of an analysis of the relationship of underweight and overweight to blood pressure level classified below and above 140 mm in diabetes and in diabetes with hyperthyroidism

individuals of the same age In my own series of 1828 cases of diabetes the blood pressure was the same as in normals below and including the fourth decade, above this age the incidence of high blood pressure was greater in diabetics

4 In my series of 443 cases of diabetes associated with hyperthyroidism 37.6 per cent of the patients had a blood pressure below 140 mm and 62.4 per cent had a blood pressure above 140 mm against 54.3 and 45.7 per cent respectively in diabetes not associated with hyperthyroidism

5 In my series of cases the diabetics up to 30 years of age showed hypertension only in 9 per cent whereas in diabetics with hyperthyroidism, hypertension was present in 42 per cent of

this group of young individuals Up to the fifth decade, hypertension in itself presents no marked incidence of diabetes, after the fifth decade the incidence rises markedly

6 In 50 cases of hypertension in my series, glycosuria was present in 36 per cent In 50 glucose tolerance tests on these individuals, 39 per cent showed glycosuria in the presence of a normal curve and 55 per cent showed no glycosuria in the presence of a diabetic curve

7 The renal threshold in cases of hypertension is high

8 A close relationship exists between hypertension and diabetes, and hypertension occurs more frequently in diabetics than in non-diabetics

The Fallacy of the Weighed Diet in the Treatment of Diabetes Mellitus*†

By HELMUTH ULRICH, M D , F A C P , *Boston, Massachusetts*

THE weighing of food is regarded as a great hardship by nearly all sufferers from diabetes mellitus, and I have become convinced that it is a burden they should not be required to bear. Hairsplitting figures concerning carbohydrate, protein and fat may make a fine appearance in a published article, but it is unlikely that they ever represent the actual conditions that obtain in the patient's kitchen. I am sure that the weighing of food is practiced much less than it is preached.

Weighed diets are prescribed because they are supposed to make possible an accurate computation of the nutritive value of the food that is eaten by the patient. In order that the expenditure of time and energy required for the process of weighing shall be warranted it is necessary to prove, (1) that the accuracy that is assumed to accrue is actually attained, (2) that the degree of accuracy, if achieved, is sufficiently great to pay for the effort, (3) that good results can not be obtained by a simpler method.

Concerning the first of these, the at-

tainment of accuracy, it may be natural to assume offhand that careful weighing of the food enables one to know exactly the amount of carbohydrate, protein and fat that is absorbed by the body and the number of calories derived therefrom, but it requires very little ingenuity to expose the fallacy of such an assumption. There are too many variables.

One of them is the process of digestion and absorption. It varies with different persons and in the same person at different times. Changing nervous and mental states, the varying activities of the gastrointestinal canal and its accessories, the effect of the composition of the diet on the rate and other phases of digestion, and probably many other known and unknown influences are involved.

The amount of cellulose in the diet, for example, is said to have a bearing on the utilization of protein and other foods. Also, slow absorption of a certain amount of carbohydrate, taken as slowly digested starch, appears to have less influence on the level of the blood sugar than rapid absorption of the same amount of carbohydrate taken as easily assimilated dextrose.

That is illustrated by table I which shows the difference between the changes of the level of blood sugar pro-

*From the Evans Memorial for Clinical Research and Preventive Medicine, Boston University School of Medicine, and The Massachusetts Memorial Hospitals, Boston.

†Received for publication, October 20, 1931.

duced in two fasting patients after the ingestion of 50 grams of dextrose and an equivalent amount, 250 grams, of boiled potato. In case I the blood sugar increased 86 per cent following dextrose and 50 per cent after the potato, in case II it increased 100 per cent after dextrose and only 50 per cent from the potato.

An important error in the process of weighing is introduced by the variable composition of items of food. Superficial study of any of the tables of food analyses will support this assertion.

Take the item of meat, for example. The much quoted tables by Atwater and Bryant¹ indicate, as shown in table II, that there are great variations in the composition of cooked beef.

Similar differences are found with other foods. The sugar in orange juice varies from 5.04 to 14.3 per cent,² the carbohydrate, exclusive of fiber, in the edible portion of carrots has a variation of from 5.9 to 11.5 per cent,* beets

*All data of analyses contained in this article are taken from Atwater and Bryant's tables, unless it is stated otherwise.

vary from 3.2 to 14.4 per cent and parsnips from 6 to 14.2 per cent. Even eggs, seemingly so uniform, vary in protein from 11.4 to 17.4 per cent, and in fat from 8.6 to 15.1 per cent.

Table III shows the variations that may occur in a day's ration designed by Joslin³ to contain 30 grams of carbohydrate, 48 grams of protein and 119 grams of fat. Theoretically it supplies 1,383 calories.

As a basis for constructing the table I have assumed the possibility that on certain days the ration may contain the minimal food values given for each item by Atwater and Bryant and others, and on other days the maximal values. For the estimation of the caloric value and its variation, however, I have combined the maximal amount of fat with the minimal amounts of protein and carbohydrate of each item, and vice versa, except in the case of fruits and vegetables. That is to say, a portion of meat with much fat usually contains a correspondingly small amount of protein, but fruits and vegetables that are high in protein are likely

TABLE I
Difference between the Changes of the Level of the Blood Sugar, in Milligrams per 100 c c
Following Ingestion of 50 Grams of Dextrose and 250 Grams of Boiled Potato

TIME	CASE 1		CASE 2	
	DEXTROSE	POTATO	DEXTROSE	POTATO
Before	307	334	200	148
1 hour	400	364	307	190
2 hours	571	444	363	222
3 hours	500	500	400	210
4 hours	400	444	307	190
5 hours	307	308	250	174
Rise in mg	264	166	200	74
Rise per cent	86	50	100	50

TABLE II
Variations in the Composition of Cooked Beef (Atwater and Bryant)

	PROTEIN	FAT	FUEL VALUE PER POUND
Roast Beef	14.5 — 29.7%	19.6 — 41.4%	1210 — 2030 Cal
Round Steak	20.3 — 34.1%	3.3 — 16.9%	615 — 1170 Cal
Loin Steak	20.6 — 26.6%	11.8 — 35.7%	925 — 1875 Cal

TABLE III
Variations That Are Possible with a Carefully Weighed Diet Planned to Contain 30 Grams of Carbohydrate, 48 Grams of Protein and 119 Grams of Fat

	GRAMS	CARBOHYDRATE		PROTEIN		FAT		CALORIES	
		MIN	MAX	MIN	MAX	MIN	MAX	MIN	MAX
Bacon ^a	30	0	0	19	54	7.5	15	89	143
Egg (one)		0	0	5.7	8.7	4.3	7.5	73	90
Chicken ^b	45	0	0	7	11.4	0.7	12.7	52	142
Meat ^c	45	0	0	6.8	15.3	1.5	34.1	75	334
40% cream ^d	150	2.2	4.5	3.1	3.3	60	63	571	588
Grapefruit ^e	200	9.2	17	0.6	1.2	0.2	0.4	41	76
Lettuce	50	0.6	1.9	0.3	0.9	0.1	0.3	5	14
5% vegetables	420	7.1	26.9	0.8	25.2	0	5.9	32	261
Butter ^f	30	0	0	0.1	1	23.3	26.1	214	235
Total		19.1	50.3	26.3	72.4	97.6	165	1151	1883

^aThe fat content of fried bacon is estimated. Accurate data are not available.

^bIncluding fowl.

^cCooked beef only. Satisfactory data for other cooked meats are not available. If other meats were included the variations would probably be greater.

^dPercentages of fat in 40% cream were supplied by H. P. Hood and Sons, Boston, percentages of carbohydrate and protein are from data supplied by Massachusetts State College and from Joslin.³ The figures given here apply to 40% cream only, if ordinary heavy cream were used the variation of fat would be much greater.

^eData for grapefruit are from Chatfield and McLaughlin.²

^fData for butter were supplied by Massachusetts State College.

to be high in carbohydrate, also. This adjustment makes the variations of the caloric values given on the table much less fanciful.

I readily grant that the grouping of all minimal or all maximal values on any one day must be looked upon as an academic possibility only. Usually the extremes will have a tendency to balance each other and form a more or less constant daily mixture. But that means that it is not the weighing but the law of chance that determines the relative uniformity of the diet. The same law would operate if a simpler method were used.

A majority of the foods have been analyzed in their raw state, but cooking has a profound influence on their composition. It removes much of the carbohydrate from vegetables and much fat from meats.

For an illustration let us take bacon. Smoked, uncooked bacon is listed as containing from 40 to 79.7 per cent fat, which in itself is a large variation,

amounting to a difference of about 90 calories in a serving of one ounce. Fried bacon (not listed by Atwater and Bryant) is assumed to contain about 40 per cent of fat by Campbell and Porter,⁴ and 50 per cent by Joslin³ and Huddleson.⁵ How closely this is approached depends on the degree of frying. Estimates based on the loss of weight resulting from the frying indicate that crisp bacon may contain as little as 25 per cent of fat and lightly fried bacon as much as 50 per cent. In regard to vegetables, von Noorden long ago called attention to the great loss of carbohydrate that was brought about by the process of cooking. He stated that raw spinach, for example, contains 2.97 per cent of carbohydrate, cooked spinach only 0.85 per cent.

Another uncertainty, a very important one, is introduced by the patients' inability or unwillingness to carry out orders. Intentionally or not they frequently break a set of rules or a dietetic prescription. The unintentional

violations may be eliminated by training, control of the wilful infractions is more difficult. I am convinced that a dietetic prescription that requires weighing of the food is broken more often than one that is carried out more easily. The order to weigh food, therefore, may defeat the very purpose for which it is given.

All this shows that accuracy can not be achieved by the use of the scales.

It may be argued that the weighing method, although admitted to be not wholly accurate, may nevertheless approach accuracy more closely than any other method. This must be conceded, at least in theory. It brings us to the consideration of the second and third postulates stated at the beginning, namely, that the degree of accuracy must be sufficient to pay for the effort, and that good results can not be obtained by a simpler method.

They may be considered together, because they are interdependent. If weighing of the food is the only method by which a reasonable degree of accuracy can be reached, then the scales must be used, but if a simpler method is nearly as accurate, then the expenditure of time and energy required for the process of weighing is not warranted.

When I began to treat diabetes I followed the prevalent custom of prescribing weighed diets, but I abandoned that method very soon. During the past ten years I have not asked one of my patients to follow it. I am using more easily understood household measures and natural food units in my dietetic prescriptions. The menu given in table IV is an example. The percentages of carbohydrate, protein and fat in this table are rough approxima-

tions only, but I am confident that they are nearly as accurate as if the food had been weighed with the utmost care.

This statement is supported by the results obtained with a group of patients who received an unweighed diet and whose level of the blood sugar was determined on several consecutive mornings before breakfast. A comparison of these results with others obtained with patients receiving a weighed diet showed no significant differences in regard to the daily variations of the blood sugar.

I am aware that dietetic prescriptions by weights and calories are easier for the physician. I use them constantly in the hospital where the services of a trained dietitian are available. Outside of the hospital, however, the burden of translating such a prescription into a day's menu is placed on the patient. A few patients have sufficient leisure, inclination and intelligence to do it in a satisfactory manner; many more have not. They should not be required to perform a task that properly belongs to the physician.

The many and changing systems of the dietetic treatment of diabetes give support to the thesis that burdensome attention to minute details is not necessary. Sansum⁶ prescribed high carbohydrate diets, Newburgh and Marsh⁷ advocated high fat diets, Allen depended on starvation, and all of us allow more carbohydrate now than we did in the past. Rabinowitch⁸ has recently emphasized again that slight undernutrition, stressed also by Allen⁹ and others, appears to be more effective in the treatment of diabetes mellitus than painstaking attention to the percentage composition of the diet.

TABLE IV
A Day's Ration by which Approximate Accuracy Is Reached without the Use of the Scales

	CARB	PROT	FAT	CAL

Myxedema

A Case Report*

By HENRY B GOTTEN, M D, *Memphis, Tennessee*

CLASSICAL myxedema is seldom seen. The case reported herein is interesting in that it presents practically all the characteristics of an extreme hypothyroidism.

Mrs W D H, aged thirty, came to the clinic on November 17, 1930, complaining of exhaustion, lack of energy, and weakness, and stating that these symptoms had persisted since the birth of her last child, seven years earlier. She had spent a part or all of each day in bed for a number of years. During that time she had gained about thirty pounds in weight. Menstruation was irregular, the periods appeared every six to eight weeks and were very scant. Her eyes often became very puffy, and her feet were sometimes swollen. She suffered a great deal from colds and was always chilled. Her digestion was very poor; she was unable to eat sweet or greasy foods, was frequently troubled with nausea and vomiting, and for a long while had been severely constipated. On one occasion she had had an acute attack of colic.

The patient was five feet, one inch in height and weighed one hundred thirty pounds. Her skin was pasty in color, was cold, dry, puffy, and did not pit on pressure. A moderate anemia was obvious. Blood pressure was 110/70, pulse 70, and temperature 98 degrees. Reflexes were markedly retarded, particularly on relaxation. Psychic response was sluggish. No other physical signs were found.

The laboratory test of the urine was reported negative. The white blood count was normal, but the red blood count was only 3,400,000, and the hemoglobin 52 per cent.

The basal metabolic rate was minus 42. Roentgenograms of the skull were negative.

The heart was typically myxedematous, being grossly enlarged. The right side measured 57 cm and the left 112 cm,—a total of 169 cm (figure 1). Electrocardiographic tracings revealed a right axis deviation with slurring of the Q R S complexes in all three leads. The voltage was low (figure 2).

Four grams of desiccated thyroid were given each day for a period of two months. During that time the patient improved rapidly. The reflexes returned to normal. Her weight decreased to 110 pounds. The hemoglobin increased to 70 per cent, and the red cell count rose to 3,800,000. At the last examination the pulse rate was 100. The metabolic rate was plus 10. The heart had become normal in size, as shown by the roentgenogram: the right side measured 25 cm and the left 9 cm,—a total of 115 cm (figure 4). The electrocardiograph was considered normal. The Q R S complexes were upright in leads I and II and inverted in lead III, which was interpreted as an axis deviation. The T waves were upright in all of the three leads (figure 3).

Several factors in this case are sufficiently interesting to warrant discussion. The dullness and listlessness characteristic of hypothyroidism were present. Although the psychomotor activity was decreased, the senses were

*Received for publication, September 12, 1931.

normally acute and the mentality seemed unimpaired. Retardation of the reflexes, especially of the Achilles reflex, was one of the findings. The secondary anemia was outstanding, practically all symptoms could have been explained on the basis of pernicious anemia. The cardiac enlargement also marked the disease.

The retardation of all reflexes is a pathognomonic finding of myxedema. The condition is particularly evident on relaxation of the Achilles reflex and may be easily recognized without the aid of mechanical devices.

The first published account of this phenomenon was recorded in 1924, by W. C. Chaney.¹ He found that the kymograph demonstrated a slow Achilles reflex as compared to the normal. Since Chaney showed that in

other diseases characterized by a lowered metabolic rate, as pituitary tumor, this reflex is not retarded, it is always advisable to test the Achilles reflex when the patient has a low metabolic rate. In the more severe forms of anemia, this reflex is normal. Myxedema may thus be further distinguished from pernicious anemia.

An erroneous diagnosis of pernicious anemia is often made in myxedema. Each of the three cases reported by MacKenzie had previously been diagnosed pernicious anemia. Error is especially likely if examination of the gastric contents reveals no free hydrochloric acid. Although hydrochloric acid is present in many cases of myxedema, it is not always a finding, therefore one cannot distinguish myxedema and pernicious anemia by its absence.

FIG 1 Heart in case of myxedema before treatment

Each of twenty-three patients reported upon by Stone was anemic to some extent, in a few the hemoglobin was as low as 40 per cent. The gastric secretions of several contained no trace of hydrochloric acid.

The characteristics of pernicious anemia as opposed to those of the anemia of myxedema are (1) the presence of macrocytes and megalocytes, (2) the high color index, (3) the abnormal appearance of the red blood cells, (4) spinal cord changes, (5) a normal metabolic rate, and (6) a history of remissions and exacerbations of symptoms. The age of the patient is

also a consideration. Pernicious anemia seldom develops in persons so young as the patient in this case.

Zondek⁸ first reported cardiac enlargement in myxedema in 1918 in Germany. In this country it was described by Fahr⁵ in 1925. Davis³ recently collected twenty-one cases in the literature, to which he added another of his own. The enlarged heart, therefore, is now recognized as a feature of this disease.

In the myxedematous heart the chambers are equally dilated. Neither the bulging of the conus arteriosus and pulmonary arteries of mitral stenosis,

FIG 2 Electrocardiographic tracing in a case of myxedema before treatment. Note low voltage, flat T waves, and increased P-R interval (almost 0.2 sec.)

FIG 3 Electrocardiographic tracing in case of myxedema after three months' treatment. Note change in voltage and decrease of P-R interval.

nor the marked dilation of the left ventricle found in aortic lesions or hypertension, is present. The heart under the fluoroscope gives the appearance of a pericardial effusion. It has also been observed that the movements of the cardiac borders are very sluggish, in sharp contrast to the movements of the enlarged heart in other diseases.

The electrocardiographic changes in this condition are characteristic. The P waves may or may not be present, the T waves are usually negative in one or more leads. The P-R interval is abnormal in many cases. The Q R S complexes are notched, frequently inverted, and the time interval is prolonged. If proper treatment is instituted, the heart will be reduced to its natural size. The irregularities of the

electrocardiographic tracing will also disappear. Fahr described several cases in which he withdrew the thyroid substance in order to more conclusively show the effect. The heart again became enlarged and the electrical tracing abnormal. When the thyroxin was resumed, the normal characteristics of the heart returned.

CONCLUSION

Physical and laboratory findings frequently overlooked in myxedema were demonstrated in this case, indicating the necessity for a thorough investigation in order to make a correct diagnosis. The rapid response of the affected systems to appropriate treatment is typical.

“We Must Keep the Whole Organism in View”

“FINALLY, although I have been seeking a description of certain isolated phenomena occurring during the course of pneumonia, I have not been unmindful of the dictum of Professor Haldane, that in studying biological phenomena “we must keep the whole organism in view”—that the living organism is a whole, not merely a collection of its parts, and that whatever happens in one part of the body affects every other part. Moreover, experience abundantly teaches that conclusions regarding phenomena that occur in the test tube cannot be applied to the living body without reservations, and that what happens in one animal under certain circumstances does not necessarily happen in another under similar conditions. The conditions can never be identical. Biological phenomena can never be fully understood unless in addition to the study of isolated phenomena the “physis” also be studied, and by “physis” the Greeks meant “the organism—the organism as a whole.” It is this element that medicine must not disregard, but experience teaches that we can best understand the whole by the study of the parts, not as isolated events, but in their relation to the entire organism.”

Hypothyroidism Without Myxedema*†

By JOHN B. YOUNG, M.D., F.A.C.P., and SAMUEL S. RIVEN, M.D.,
Nashville, Tennessee

DURING recent years considerable evidence has accumulated to emphasize the importance of hypothyroidism without myxedema as a separate clinical entity. A growing number of case reports and articles dealing with this condition indicates an increasing appreciation of its frequency and importance. Many of the reports have been from regions where goiter is common but the report of Thompson and Thompson¹ from the New England States, King² from Baltimore, and Higgins³ from Virginia show that the condition is not confined to such areas. The present report from a region where the general incidence of goiter is relatively low gives further evidence of the wide spread distribution of this condition.

However, in spite of this increasing interest, the disease is frequently overlooked because of the absence of signs and symptoms common to the better known form of hypothyroidism, myxedema. Patients with hypothyroidism without myxedema, characteristically present few or none of the better known signs and symptoms of hypofunction of the thyroid. The skin is

usually not dry, harsh, or thick, loss of hair seldom occurs. The patient is not unduly sensitive to cold, and the temperature is not subnormal. The pulse is not slow and may even be more rapid than normal. Hoarseness and mental lethargy, so frequently present in myxedema, are lacking. The disease may occur at any age but many of the patients are young or adolescent. Very often the symptoms are misleading, suggesting disease of other organs and systems and the primary location of the trouble in the thyroid gland is unsuspected. In many instances the accidental discovery of a low basal metabolic rate has been the first clue to the true nature of the trouble.

Nevertheless, these patients do present certain symptoms, or symptom complexes, which should suggest the possible presence of this type of hypothyroidism, particularly if more common causes for these symptoms cannot be found. The most frequent and important of these are constipation, nervousness, poor emotional control, fatigability, lack of energy, and vague pains localized in various regions. The onset of the disease is gradual and insidious and may date back a number of years. Women are more frequently affected than men. The patient never appears acutely ill and the vagueness

*From the Department of Medicine, Vanderbilt University Medical School.

†Received for publication, September 15, 1931.

of the symptoms, together with the absence of significant findings on examination may lead to the diagnosis of a psychoneurosis. The constipation is very intractable and is, perhaps, the most frequent symptom encountered. Nervousness, irritability and lack of emotional control are frequently presenting symptoms. Associated with this nervousness there is a certain lack of energy and endurance, mental as well as physical. This is particularly noticeable in the exhaustion which may follow the performance of the daily duties. Warfield⁴ has described well the active individuals whose energy is forced, and whose activity is followed by an abnormal weariness. To these symptoms may be added loss of weight, a change which is the opposite of that expected in hypothyroidism. This loss of weight, together with nervousness and a not infrequent increase in the pulse rate, may lead to the suspicion of thyrotoxicosis, which is rather startlingly contradicted by the finding of an abnormally low metabolic rate.

Laboratory examinations yield little of significance except the evidence of an abnormally low basal metabolic rate, which ranges from about the lower limit of normal to as low as minus 30 per cent or lower. This, although not pathognomonic of this condition, is the most characteristic finding and is necessary for the diagnosis. Of almost equal importance is the response to treatment with thyroid substance. The significance of these two factors is discussed more fully below. Warfield and Greene,⁵ and others, have described a secondary anemia of the chlorotic type, frequently associated with this type of hypothyroidism. While a secondary

anemia is common in this condition, it is not always present nor is it, of course, sufficiently characteristic to be of particular diagnostic significance.

Considerable confusion exists in regard to the finding of lowered metabolic rates in association with the menopause and other conditions. While it is undoubtedly true that lowered metabolic rates may be the result of other causes than primary hypothyroidism it is likewise true that the latter may occur with other diseases as an associated, not independent, condition.

A correct diagnosis of hypothyroidism is important because of the relief of symptoms which follows specific treatment with thyroid substance, a relief which is so definite that, as will be shown below, it is an important factor in determining the correctness of the diagnosis. It is also important that the diagnosis be made as early in the disease as possible in order that early treatment may prevent the development of structural changes in various organs and tissues, from long continued hypofunction of the thyroid. The effect of such hypofunction of the thyroid on the gastrointestinal tract has been emphasized by Brown.⁶ Barrett⁷ has called attention to the effect on the nervous system. Williamson and Pearse⁸ believed that the functional strain incident to long continued hypofunction is important in causing structural changes in the thyroid gland itself.

The following case reports are presented to illustrate various types of cases and different features of the disease. They have been selected from a total of seventeen cases of this condition observed in this clinic during the

past three years, most of which have been followed for a period of two years or more. In addition to the case reports the significance of certain laboratory findings, the effect of treatment and the relation of this disease to other forms of hypothyroidism are discussed.

REPORT OF CASES

Case I V G, aged 25, a single, white woman was admitted to the medical outpatient department complaining of headaches, nervousness, and pain in the arms. The present illness had begun about seven months before when she first noted a dull aching pain over her head and left side of the face gradually increasing in severity. Increasing restlessness and insomnia were noted. For a year she had been unable to follow her usual occupation of teaching. There was a history of vague gastrointestinal symptoms associated with constipation for several years. The average weight was 132 pounds, and her weight was 128 pounds at the time of her first examination. There was no history of any menstrual disturbance.

Examination revealed a well-developed, well-nourished white female who was cooperative and mentally alert. There was some tenderness over the scalp but none over the sinuses. The pupillary reactions were normal. There was a slight external strabismus of the left eye. The sclera were clear, and the examination of the fundi was negative. The tonsils were small, smooth, not infected. There was a severe gingivitis about many of the upper teeth and diffuse dental caries. The thyroid was not enlarged. Examination of the chest and abdomen gave normal findings. The blood pressure was 126 systolic and 84 diastolic. The skin was soft, warm, dry, clear and of good tone. The neurological examination was negative. All the usual laboratory tests, including the urinalysis, the blood count and the Wassermann reaction, were negative. A tentative diagnosis of psychoneurosis was made, and she was treated with a mild sedative, but did not improve.

On March 16, 1929, she returned to the clinic with the same symptoms as those described a year before. This time a basal

metabolism determination was made, and to the surprise of the observer, the rate was found to be minus 26 per cent. Four days later it was minus 25 per cent. At this time it was thought there was perhaps a slight dryness of the skin, and a thinning of the outer half of the eyebrows. The patient appeared somewhat apathetic and complained of mental sluggishness. There was no edema, and no alteration in weight. A diagnosis of hypothyroidism was made.

Course She was first given thyroid extract 0.13 gms (gr two) daily. On March 30, 1929, the basal metabolic rate was minus 19 per cent. The thyroid extract was increased to 0.065 gms (gr one) three times a day. On April 6, the basal metabolism was minus 10 per cent. The patient said she felt very much improved. Her bowels moved regularly and there was a general feeling of well-being. The thyroid extract was discontinued. On April 16, 1930, she returned with the symptoms of indigestion, fatigability and mental sluggishness. The basal metabolism determination was minus 29 per cent. She was again given thyroid, 0.065 gms (gr one), three times a day. On the 27th of April, she said she felt better, the bowels were regular, the appetite was good and the basal metabolism was minus 21 per cent. The same dose of thyroid extract was continued and on May 25, the basal metabolism was minus 8 per cent. On June 17, she still felt better as compared to first visit, but not as well as at the last visit. The basal metabolism was minus 18 per cent. On August 21, 1929, the patient was seen again with a return of all of her symptoms. She had discontinued thyroid medication and was back where she had started, with a basal metabolic rate of minus 29 per cent.

Comment There is presented a young woman with a metabolism rate within the "myxedema range", who nevertheless showed no myxedema, no change in weight, no menstrual disturbances, and only slight dryness of the skin. Many of the common symptoms of myxedema were lacking. She responded favorably to the administra-

tion of thyroid extract but never had enough to bring the basal metabolism up to normal. Discontinuance of the drug was associated with a return of the clinical features of the disease. Except for the finding of a low metabolic rate and the response to specific therapy there was little to indicate the existence of the hypothyroidism.

Case II B T, white female, aged 48, was seen in the medical outpatient department July 7, 1929, complaining of nervousness, insomnia, increasing irritability and moroseness. In addition she had severe headaches in the back of her head. The menopause had begun some two years before and the uterus had been removed a year before admission. Examination revealed a well-developed, and well-nourished woman. The examination of the ears, eyes, nose, and throat was negative. The thyroid isthmus was distinctly enlarged, but the lobes were barely palpable. The remainder of the examination was normal. The blood pressure was 140 systolic and 80 diastolic. The weight was 115 pounds. The skin was fine in texture, elastic, of good quality, and normally warm and moist. A tentative diagnosis of psychoneurosis was made but the basal metabolism was found to be minus 17 per cent. A second test the following day was again minus 17 per cent. The patient was given thyroid extract, 0.1 gm (gr one and one-half), daily, and in three weeks the basal metabolic rate had risen to plus 5 per cent. The thyroid extract was discontinued for ten days and the basal metabolism promptly dropped to minus 26 per cent. Thyroid extract was then given in doses of 0.065 gms (gr one) three times a day for three days and 0.065 gms (gr one) twice daily for three days and then 0.1 gms (gr one and one-half) daily. On September 19, the patient returned feeling quite well. The basal metabolic determination was minus 7 per cent. Thyroid extract 0.1 gms (gr one and one-half) daily was continued during a period of fifteen months, the basal metabolism ranging between minus 8 and plus 1 per cent. On October 3, 1930, she came for a chat say-

ing she was very much improved and had continued to take thyroid extract, 0.1 gms (gr one and one-half), daily.

Comment This case is an example of a lowered metabolic rate following the menopause. Because of the favorable response to treatment with thyroid extract, both subjectively and in the effect on the metabolic rate, a diagnosis of hypothyroidism independent of the menopause is warranted.

Case III Z M, a married woman, aged 42, was admitted to the medical outpatient department on August 2, 1929, complaining of nervousness, and mental depression. All her life she had been more or less nervous as were many members of her family. Ten months before her admission, her menstruation had ceased and two months later she had had influenza. Following the attack of influenza she felt weak, much depressed emotionally unstable, and was forced to stay in bed for two months. One month before her admission, she had had a severe menstrual period lasting four days. Following this the nervousness increased, her appetite was poor and she lost weight. There had been no noticeable skin changes, and no constipation. The physical examination was essentially negative save for emaciation, she weighed only eighty-nine pounds. The urinalysis and Wassermann tests were negative. The blood showed a moderate secondary anemia with a hemoglobin of seventy per cent. A tentative diagnosis of psychoneurosis and undernutrition was made. The patient was treated with sedatives and psychotherapy but made no progress. On October 12, the basal metabolism was found to be minus 11 per cent. She was given thyroid extract, 0.38 gms (gr one-half), twice a day and improved somewhat. On December 2, the basal metabolic rate was still minus 11 per cent and the thyroid extract was discontinued. Within one week the rate dropped to minus 20 per cent. Thyroid extract was again given in doses of 0.38 gms (gr one-half) three times a day, but this amount produced no change in the basal metabolic rate and few changes in the symp-

toms On January 27, 1930, the basal metabolic rate was minus 22 per cent It was decided to push the drug and she was given 0.13 gms (gr two) daily The basal metabolism rose to minus 10 per cent, the patient felt very much improved, began to gain weight and the nervousness disappeared By April 10, 1930, she had gained eight pounds, the metabolic rate was minus 1 per cent and the thyroid extract was continued On June 10, the basal metabolism was minus 6 per cent, her weight was 102 pounds and she felt well The thyroid extract was reduced to 0.065 gm (gr one) and 0.13 gm (gr two) on alternate days She was observed from August to October during which time she continued to improve, the basal metabolism ranging from minus 6 to plus 6 per cent During that interval she gained 6¼ pounds

Comment This patient was very much improved with thyroid extract, and such features as loss of weight, nervousness, and mental sluggishness disappeared Symptoms referable to the menopause were little affected It is interesting to note that an initial low metabolism became even lower after thyroid medication, once started, was discontinued, and that rather large amounts of the thyroid extract were necessary to raise the metabolism to a normal level The significance of these observations is more fully discussed below The administration of amounts sufficient to raise the metabolism to normal was necessary to secure subjective improvement

Case IV J T, woman, aged 20, was admitted to the medical outpatient department on September 3, 1929, complaining of nervousness and abdominal distress An appendectomy had been performed for these symptoms with no relief Her appetite was variable and for a long time she had suffered with constipation She was troubled with disturbed sleep and worried a great deal

The examination revealed a well-developed,

well-nourished young woman of normal weight (112 pounds), who was very emotional and apprehensive The skin was coarse and dull, the mucous membranes were pale The eyes, ears, nose, and throat were essentially normal The thyroid was slightly enlarged at the isthmus, otherwise normal The examination of the heart and lungs was normal The blood pressure was 105 systolic and 45 diastolic There was a scar in the right lower quadrant of the abdomen, but no tenderness, no spasm, no masses and no palpable organs

The tentative diagnosis was a functional disturbance of the gastrointestinal tract, constipation and mild secondary anemia Treatment was directed toward these, but with no improvement On her third visit to the clinic a basal metabolism determination was obtained and the rate was minus 17 per cent A check determination on October 5, was minus 23 per cent She was then given thyroid extract 0.065 gms (gr one) three times a day After one week the rate rose to minus 3 per cent The patient was advised to continue with thyroid extract, 0.13 gms (gr two) daily and a week later the metabolism dropped to minus 10 per cent The dose of thyroid was increased to 0.2 gms (gr three) daily, and the metabolic readings varied from minus 17 per cent to plus 3 per cent, depending on how conscientious she was about taking her medication Finally her symptoms were controlled with 0.13 gms (gr two) of thyroid extract daily The course of observation lasted over a period of eight months and space does not permit enumeration of the numerous metabolism readings It must however, be mentioned that there were times, when the metabolism approached normal that the patient had nervousness and mild tremor The best symptomatic improvement was observed with the basal metabolism at a level of minus 3 per cent During the period she was receiving thyroid extract she gained weight and the emotional instability and constipation were controlled

Comment A young woman with none of the usual findings in the history and examination suggestive of myxedema was found to have a dis-

tinctly lowered metabolic rate and showed a decided improvement when given thyroid extract

Case V A H, a white woman, aged 33, was admitted to medical outpatient department on September 13, 1929, complaining of a dull pain around the heart which had been present for 18 months and was not particularly related to exertion or excitement. There was no history of rheumatic fever. At times she felt weak, apathetic and fatigued, at others was very nervous and "jumpy". There had been a slight loss of weight (6 pounds). She had had frequent headaches in the past. There was no constipation. The menstrual history was normal.

Examination revealed an alert, healthy appearing young woman. Her skin was clear, smooth, and not cold. The examination of the heart and lungs was normal. The blood pressure was 105 systolic and 65 diastolic. Abdominal and pelvic examinations were negative. The Wassermann test and urinalysis were negative. The electrocardiogram was normal. The blood showed a slight secondary anemia, with the hemoglobin 66 per cent and the red blood cells 3,480,000. A tentative diagnosis of effort syndrome was made. On September 29, the basal metabolism was minus 28 per cent. She did not return to the clinic again until March 18, 1930, when the basal metabolic rate was found to be minus 24 per cent. The symptoms were the same.

Although this patient was not treated with thyroid extract the abstract is presented because there is illustrated an individual in the fourth decade of life, with no menstrual disturbances, no skin changes, without sensitiveness to cold, with certain symptoms such as emotional instability, fatigability and vague pains which are commonly seen in this type of hypothyroidism and an initial metabolic rate of minus 28 per cent. After a period of seven months without treatment, the same symptoms of hypothyroidism remain, the metabolism

is minus 28 per cent and there is no myxedema.

DISCUSSION

The existence of a syndrome such as that described above has naturally aroused discussion as to the exact relation between this and other forms of hypothyroidism and numerous classifications of the latter have been suggested. The most recent is that of Warfield,⁴ who divides hypothyroidism into three main groups: cretinism, myxedema of adults, and masked or occult hypothyroidism, the latter the condition which has been described here. Whether or not this hypothyroidism is to be considered a forerunner of myxedema or a premyxedematous stage of myxedema is questionable. Several of our patients have been observed over a period of months without the development of myxedema even though untreated. If one may judge from the history, the condition in some patients may have been present for years without the development of myxedema. Such evidence is not entirely convincing, however, since myxedema may be very gradual and insidious in its onset. Other evidence, however, supports the view that this type of hypothyroidism exists as an independent syndrome. The existence of a metabolic rate as low as minus 30 per cent for considerable periods of time without the appearance of myxedema is very suggestive. The occurrence of a definitely lowered metabolism in such conditions as inanition and the like without the presence of myxedema, with associated structural changes in the gland, is also important. Of particular interest in this connection is the work of Williamson and

Peaise⁸ who have described a specific pathologic change in the gland in myxedema, and who distinguish on the basis of these pathological studies between myxedema and other forms of hypothyroidism

Some question may be raised as to the justification of the diagnosis of hypothyroidism when the above symptoms and a lowered metabolic rate are found in association with such conditions as the menopause or various other disease states. Since the symptoms are not particularly characteristic it becomes largely a matter of interpretation of the lowered metabolic rate, the significance of which is more fully discussed below. Thurmon and Thompson⁹ have recently stated that in many of these cases there is no primary hypothyroidism. We agree that this is true in many instances and the correctness of this view is supported by the failure in many cases, of thyroid substance to relieve the symptoms even though the basal metabolism is brought by this means to normal levels. We believe, however, that in certain cases, an independent hypothyroidism may exist in association with such conditions as the menopause and in these cases, existence of a primary thyroid disease as a cause of at least part of the syndrome is borne out by the improvement in certain of the symptoms by the administration of thyroid extract. Case two is an example of such an instance.

It is apparent that in the absence of characteristic symptoms and physical signs, great dependence is placed on the finding of a low basal metabolic rate. It is important, therefore, that the significance of this laboratory finding be clearly understood. Low basal meta-

bolic rates do not always mean hypothyroidism. They may be observed in trained subjects (because the usual clinical standards are too high for this group), in inanition, and with loss of muscular tone, as well as with disturbances of other glands of internal secretion. Thurmon and Thompson⁹ have recently classified patients with low basal metabolic rates into three groups, as follows: (1) those who are apparently healthy and have a low metabolism, (2) those with hypothyroidism too mild to result in myxedema, and (3) those in whom a lowered metabolism is associated with a pathological condition other than underfunction of the thyroid. We are in accord with this classification but emphasize that low rates mean hypothyroidism if the first and third group are ruled out, and further, that the determination of the basal metabolic rate is not only of great importance but a necessary means of making such a diagnosis. The common errors in the determination of the basal metabolic rate give falsely high values rather than low, and with rare exceptions falsely low rates cannot be obtained. Boothby and Sandiford,¹⁰ in a series of what they call questionable hypothyroidism, found in eighty-six cases an average below minus 20 in thirty, and below minus 11 in sixty-one instances. Means and Burgess¹¹ state that a low basal metabolic rate means hypothyroidism provided hypopituitarism, Addison's disease, starvation, et cetera, are ruled out. Therefore, in the absence of such conditions, with basal metabolic rates below minus 20, without frank myxedema, but with the symptoms mentioned above, a diagnosis

of hypothyroidism of the type described in this paper must be considered. The main difficulty of interpretation occurs in the case of individuals with a rate between minus 10 per cent and minus 20 per cent. In such instances we feel that in the presence of symptoms such as fatigability, mental sluggishness and constipation, a metabolism of minus 10 per cent or less strongly suggests hypothyroidism provided that the symptoms are relieved by the administration of thyroxin or thyroid extract coincident with a return of the basal metabolic rates to normal levels. If we interpret it in this way, a low metabolism may be safely used in this diagnosis.

Of particular importance in connection with the finding of basal metabolic rates in the neighborhood of minus 10 per cent are the observations in cases two and three. It will be noted that when treatment with thyroid substance was stopped after a short period of administration, the basal metabolic rate which had been minus 17 per cent in case two, and minus 11 per cent in case three, fell within a short period to a much lower level. The following explanation for this finding is suggested. There is evidence for the belief that the administration of thyroid substance to a normal subject leads to a certain amount of decreased function and atrophy of the gland. In the cases described it may be that the thyroid gland, though functionally insufficient, was able by straining to maintain the metabolism at a near normal level. Relieved of the stimulus to this activity by an artificial supply of hormone its activity fell to a subnormal level as shown by the

lower metabolic rate, when the administration of thyroid stopped. If this explanation is correct it is possible that such a procedure would be of diagnostic importance in border line or mild cases of this condition.

The nature of the response to the administration of thyroid substance or thyroxin is of great importance. As a means of establishing the diagnosis it is of even greater importance than the determination of the basal metabolism since it serves to distinguish between the lowered metabolic rates due to primary and secondary hypothyroidism. In many cases the nature of the response to the drug may be the final evidence which establishes the diagnosis. In true primary hypothyroidism the relief of symptoms is strikingly quick and complete if a proper amount of the drug is used. A return of the symptoms characteristically follows a withdrawal of the drug. The patients are able to tolerate much larger doses without the development of symptoms of hyperthyroidism than are normal subjects. In many cases the amounts of thyroid necessary to raise the metabolic rate to normal and relieve the symptoms is larger than is generally appreciated. This amount will vary in individual patients, as will the level of metabolism at which maximum relief of symptoms is obtained and both must be determined by trial for each individual. The amounts which may be necessary and which may be well tolerated are shown in the case reports presented above. Symptoms of hyperthyroidism of course occur with too large amounts and over dosage should be avoided.

In contrast to true hypothyroidism,

thyroid substance is ineffective in cases of lowered basal metabolic rate due to other causes and may even make the symptoms worse. However, in those instances in which a true hypothyroidism exists in association with other conditions, such as the menopause, the administration of thyroid substance may relieve the part of the symptoms due to the hypothyroidism, as in case two. Such a result may be considered as evidence of the existence of more than a single disease.

SUMMARY

Hypothyroidism without myxedema is a more common condition than is generally appreciated and is not confined to regions where goiter is com-

mon. Failure to recognize the disease is due to the vague symptomatology and to the fact that the signs and symptoms of the better known hypothyroid state, myxedema, are lacking. The diagnosis depends largely on the detection of an abnormally low basal metabolic rate, but this observation must be interpreted with caution since all low rates are not due to hypothyroidism. In diagnosis, the nature of the response to thyroid substance, which is specific in true hypothyroidism, is of great importance and serves to distinguish between lowered metabolic rates due to hypothyroidism and those due to other causes. Illustrative case reports are presented.

Ventricular Paroxysmal Tachycardia With Report of a Case*†

By EDWARD W. HOLLINGSWORTH, M.D., F.A.C.P., *Veterans
Administration, Hines, Illinois*

PAROXYSMAL tachycardia may be defined as an abnormally rapid heart action with sudden onset and offset, and is divided according to the site of origin of the impulse which may be in the auricle, auriculo-ventricular node, or ventricle.

In general, the important point is to differentiate those examples of ventricular origin from others inasmuch as in them the prognosis is grave. There are several points of distinction clinically between auricular or supra-ventricular, and ventricular paroxysms, the former having a practically constant rate in the various attacks and being frequently stopped by vagal pressure,¹ especially left, the latter varying in rate between various attacks and even during the same attack,² and not controlled by vagus pressure.³ A few cases of ventricular paroxysmal tachycardia have been reported as due to digitalis⁴ (where the usual dosage was not exceeded), and quinidine,⁵ but in the absence of medication are usual-

ly due to serious myocardial disease, most commonly myocardial infarction,⁶ and have frequently been produced experimentally in animals by coronary ligation.⁷

Paroxysmal auricular flutter and fibrillation are not included and can usually be detected by clinical means, the latter by its irregularity increased upon exercise, the former by sudden halving or doubling of the previous rate, which if irregular, is usually less so upon exercise.

The one positive method of identification of ventricular tachycardias is the electrocardiogram,⁸ which, however, frequently offers difficulties. If the tracings show rapid rate with abnormal QRS complexes and P waves at a different rate, or absent, or if they show onset or offset, the diagnosis may be established. As a matter of fact it is believed that P waves may not be seen or their relationship established and the showing of the onset or offset of a paroxysm would usually be purely accidental. Premature contractions may be frequent between attacks and should show complexes similar to those present during them. A further point of confusion is the frequent abnormality of QRS in tachycardia of other origin.⁹

One reports a case of paroxysmal

†Received for publication, September 3, 1931.

ventricular tachycardia with some hesitation as the diagnosis in many reported cases has been questioned by later writers. Thus Robinson and Herrmann⁶ accepted only six of sixteen as undoubted cases, Scott⁹ doubted the diagnosis in three of the four cases they reported, and Strauss¹⁰ stated only 63 undoubted cases had been reported to 1930. It is believed that but few, if any, cases have been reported having all the characteristic findings, but the following case apparently has, and is accordingly reported as such.

CASE REPORT

J. M., a white male, age 39, occupation, draftsman, was admitted to the Edward Hines Jr. Hospital, June 22, 1927, with a diagnosis of diabetes mellitus and decompensated heart. His complaints were "weak heart", difficulty in breathing, cough, rapid pulse, edema of practically entire body. Family history was negative. He had had the usual childhood diseases, and pneumonia eight years before. He was married, with wife and three children living and well. Smoked cigars, drank occasionally.

Present Illness On May 5, 1927, while spading in his garden he had a heart attack, heart fluttered and was very rapid, and he felt weak. A second attack occurred a few minutes later but the patient felt all right after resting. During the night he became short of breath, and this had continued until admission, as had edema which developed shortly after the onset. He had been treated at another hospital for heart disease and diabetes, being on a diet and receiving 15 units of insulin daily.

Physical Examination The patient was a well nourished and developed white male of 40, orthopneic, edematous and critically ill. There was diminished resonance at the lung bases and coarse râles throughout. The heart was apparently enlarged and the apex beat diffuse and wavy. Radial pulse was weak, regular, rate 150, blood pressure 146/90. There were signs of ascites and the scar of a recent abdominal paracentesis.

Laboratory Findings Urinalyses showed a

very faint trace of albumin, occasionally a faint trace of sugar, specific gravity 1.010, occasional hyaline and granular casts and red blood cells. Twenty-four hour output varied from 600 to 3,500 c.c. Glucose tolerance test showed a delayed utilization, blood chemistry was normal, Wassermann test was negative. Roentgenogram of chest showed an enlarged heart with area of infiltration at the lung bases.

Course There was slight fever from June 27 to July 3. The temperature varied from 36° to 38° C., pulse from 80 to 155, usually about 100. Pulse was noted as weak, sounds distant and feeble, on several occasions, and pulse was intermittent and irregular at times. Patient was put at rest, fluids restricted, and he was given digitalis and theobromine-sodio-salicylate. The edema practically cleared up and he was discharged August 2, considerably improved.

He was readmitted nine days later, on August 11, with edema again present, blood pressure then being 96/66. Diuretic regime was again instituted with ammonium salts and novasurol, and several doses of tryparsamide were given because of a history suggestive of syphilis and a 4 plus Kahn test. Two blood counts showed

4,460,000 red blood cells, 60% hemoglobin, 16,000 white cells, 60% polymorphonuclears, 4,360,000 red blood cells, 60% hemoglobin, 14,200 white cells, 75% polymorphonuclears. Mouth temperature showed a number of slight elevations, 37.2° to 37.4°, pulse varied from 60 to 120 with an average of 84. The edema cleared up and the patient was discharged on December 13.

He then worked steadily at a clerical position for about six months and was admitted for a third time, June 11, 1929, having been very weak, with pulse rapid, for the previous week. At that time the apex impulse could not be seen or felt, radial pulse was weak and irregular, apex rate 198 and apparently regular. The heart sounds were of fair quality and there was no edema. X-ray suggested pericardial effusion and showed a large pleural adhesion attached to the dome of the left diaphragm at junction of outer and middle thirds.

The patient was put on large doses of digitalis and on June 14 the rate was 186,

June 16, 1960, and June 18, 1960 There had been slight cough and the patient slept poorly but there was no edema, only moderate dyspnea and heart was not noticeably dilated At that time it was felt that the form of the complexes on the electrocardiogram, the variation in rate, the long duration of the paroxysm, and the severity of the heart lesion, suggested a ventricular tachycardia, and that the sudden onset during exercise in a man of sedentary habits, short and inclined to obesity, with no history of previous heart disease, suggested a coronary lesion despite almost complete absence of pain

Treatment was the same as before There were a number of paroxysms of tachycardia, the terminal attack commencing on January 29 and continuing, with but a few hours interval, until death on February 11 There was edema of the lower extremities and heart sounds were tick-tack in character On February 3 the bladder became distended,

the patient was unable to void and 1,000 c c of urine were obtained by catheterization Congestive failure gradually increased, dyspnea being only moderate and the patient conscious almost until the end

POSTMORTEM EXAMINATION

The heart was large, weighing 400 grams, dilated, particularly on the right side, there were pericardial adhesions anteriorly and considerable subepicardial fat, posterior wall of left ventricle was 15 mm thick, anteriorly the wall from the aortic ring to the apex consisted almost entirely of scar tissue, 4 mm thick, and exceedingly resistant There was a mural thrombus in the lower part, 6 by 5 cm, 14 mm thick at the apex, lamellated in the middle portion and light gray in color, and an infarct was seen some 4½ cm in diameter over the corresponding area externally (Figure 1) There was no bulging of the scar There was no evidence

FIG 1 Left ventricle opened through posterior wall, showing scar tissue and thrombus in anterior wall

of syphilis, the aortic ring showed only moderate atheroma, and coronary orifices, auricles and right ventricle appeared normal. The left descending coronary artery was followed downward for 75 cms where it entered the infarcted area and was lost. Both this and the circumflex branch were thickened, with lining rough and irregular. The right coronary showed moderate sclerosis but its lumen could be traced to the septum. The anterior $2\frac{1}{2}$ cms of the left ventricular surface of the septum showed scar tissue.

The left half of the diaphragm showed dense adhesions to the chest wall. The liver weighed 2,250 gms and was typically nutmeg. The spleen weighed 170 gms with poorly defined markings. There was much fat in the omentum and mesentery. There were 300 cc of serous fluid in the right chest.

Microscopic Examination Section through upper part of the anterior wall of the left ventricle showed muscle fibers pale, and cross striations hazy, in places replaced by fibrous tissue. There was a round cell infiltration, the cells for the most part being lymphoid with a few large mononuclears. The small vessels present showed slight intimal thickening. The larger coronaries were not included in the section. Section through the infarcted area showed practically no identifiable muscle fibers, there being almost complete replacement by fibrous tissue. New capillaries were present. There was much round cell and mononuclear infiltration and one area of anemic necrosis completely surrounded by fibrous strands. Kidneys showed a severe nephrosis, lungs, a bronchial pneumonia, liver, spleen and lungs, chronic passive congestion.

Paroxysms of Tachycardia In all seventeen paroxysms were noted, the shortest recorded duration being twenty minutes, and the longest, the terminal attack, was unusually long,⁸⁻¹¹ thirteen days. There was one of four and one of five days, and two of seven days. Abdominal, ocular and vagus pressure were ineffective. Levine³ has noted variation in the apical first sound

and irregularity in rate, the latter only being noted in this case, there being considerable variation of rate in different paroxysms and even in one which lasted for a considerable length of time.

A number of electrocardiograms were taken. The first (figure 2) was taken during the second admission, on August 24, 1927, and showed a rate of 214 with abnormal QRS, these being inverted in I and II, and T waves opposite in direction. P waves were distinct in III only, a P coming at the same rate as the QRS, immediately after the preceding QRS and 0.2 sec before the succeeding one. In this case neither onset nor offset was shown so that according to Lewis⁸ the origin cannot be determined definitely and the QRS aberration may well be due to rapid rate, al-

FIG 2 Electrocardiogram taken August 24, 1927. Ventricular rate 214, showing well marked and abnormal P waves in lead III only, at the same rate as the QRS. Paroxysmal tachycardia of an indefinite origin although abnormal QRS and their similarity to some in figure 5 suggest a ventricular one.

FIG 3 Electrocardiogram taken June 17, 1928, showing a ventricular tachycardia. QRS complexes are aberrant, P waves may be distinguished in all leads at a rate unrelated to the ventricular, and all leads show normal complexes followed by periods of tachycardia, the first beat bearing the relation of a ventricular premature contraction to the preceding normal rhythm

though similar ones are shown in a later tracing (figure 5). The tracing is very similar to one of Robinson and Herrmann's⁶ where P was distinct only in II and at half the ventricular rate. Figure 3 shows a paroxysm of tachycardia with aberrant QRS's of different form, rate 171, interrupted in all leads by normal complexes, and the auricular rate 83, P being easily distinguishable in II and bearing no constant relationship to QRS.

Figure 4 shows an electrocardiogram taken on January 24, 1929, and represents a paroxysm with a rate of 200, the QRS complexes resembling those of figure 3, but are very much higher, which is accounted for in part by improper standardization. Each alternate

T wave is high and is believed to represent a fusion of T and retrograde P. Figure 5 shows another tracing taken on September 18, 1928, and apparently represents a ventricular tachycardia with impulses arising irregularly in both ventricles and at various places in each.

A number of tracings were taken during normal rhythm, the first of which (figure 6) shows small QRS complexes, left axis deviation, inversion of T I. Electrocardiogram on June 18, 1928, (figure 7) shows a typical coronary T wave in II and III, the former coming off below the baseline and T I upright. Two days later T II and III were slightly inverted and then gradually disappeared. Both of these latter showed frequent premature contractions of ventricular origin, the QRS resembling those of paroxysms. According to Barnes,¹² these tracings would indicate occlusion of the right

FIG 4 Tracing taken Jan 24, 1929, showing ventricular tachycardia, rate 200, aberrant QRS. In II and III, alternate T waves are high due to super-imposed retrograde P waves

FIG 5 Electrocardiogram taken Sept 18, 1928, showing complexes arising irregularly from various points in both ventricles

coronary artery with infarction in the posterior and basal portions of the left ventricle, but in the present case the left artery was occluded and the anterior wall infarcted

The Relationship of Medication to Tachycardia As either a causative or therapeutic factor, this is a matter of some doubt. Paroxysms occurred while the patient was receiving digitalis in small and moderate doses, quinidine, both digitalis and quinidine, and in absence of medication. One attack stopped on the second day two hours following 0.2 grams of quinidine, a second one after two such doses, and a third attack when several doses of 0.4 grams had been given four hours apart. The terminal paroxysm was apparently uninfluenced by even fairly large doses of quinidine, although these were small compared to those recommended by Levine and Fulton¹³ who restored normal rhythm in eight of ten

cases. They strongly recommended its use, giving as much as 15 grams every five hours, and Strauss¹⁰ stated that quinidine was effective in all sixteen cases collected by him in which it was tried. Digitalis seemed to have but little effect upon the heart failure.

The evidences in this case for a ventricular origin of the tachycardia are etiological, coronary occlusion with myocardial infarction, as established by autopsy, repeated attacks of tachycardia with varying rates and abnormal QRS complexes, P waves appearing at different rates, related or unrelated to those of the QRS, premature contractions showing complexes resembling those during tachycardia. The patient's age, 39, and practically complete absence of pain are considered unusual in coronary occlusion, but the customary leukocytosis, fever and low blood pressure were present, no physical signs of pericarditis were obtained, although this was found at

FIG 6 Electrocardiogram of Oct 14, 1927, showing small QRS, left axis deviation, P-R interval of 0.2 sec

autopsy The association with diabetes is not uncommon It seems probable that the patient had his initial occlusion at the time of the onset, although electrocardiographic evidence is lacking, and later, subsequent ones with extension of the infarction Autopsy findings showed that the lesion was of long standing at least

SUMMARY

A case is reported of paroxysmal ventricular tachycardia with numerous attacks, occurring in a white male of 39, with death occurring during tachycardia one year and eight months after onset, the final paroxysm being of thirteen days duration Numerous electrocardiograms were taken and autopsy confirmed the diagnosis of coronary occlusion with myocardial infarction

FIG. 7 Electrocardiogram of June 18, 1928, showing inverted coronary T waves in II and III with low take-off in former QRS about same as in figure 6 T I now upright

Control of the Tick Borne Diseases—Methods and Economics*

By NOXON TOOMEY, M D , F A C P , *Palmyra, Mo*

A SPECIES of tick was the first arthropod proved to be a vector of disease caused by microgametic life. The relation first discovered did not involve the human body, but that of cattle. However, the discovery did afford the foundation for suppositions, based on analogy, that were soon extended to the theory of infectious diseases in man, with results that have afforded a scientific insight into the transmission of a great many of the most serious infectious diseases of man.

Apart from any consideration of ticks as possible vectors of disease to man, the diseasecommunicating tick of cattle was at once recognized to be an economic liability of almost measurable degree. Efforts to free cattle of ticks, and to keep them free, became therefore an important and actively prosecuted problem of veterinary sanitation. Tick eradictory measures were consequently devised and studied in relation to cattle infestation, but were at first prosecuted only on the cattle grazing plains of the Southwest. For a long time the idea of tick control was virtually restricted to the requirements of profitable animal husbandry.

In 1902 a species of tick was sus-

pected by L. M. Wilson and Wm. M. Chowning as being the vector of spotted fever of the Rocky Mountains.⁹ Although their epidemiological investigations served to draw attention to the wood tick as a possible vector of spotted fever, they did not succeed in establishing the theory, which was tentatively accepted by John F. Anderson in 1903, but challenged and denied by Charles Wardell Stiles in 1904.²⁰

In 1904, Ross and Milne, in Uganda, and Dutton and Todd on the Congo River, discovered that the cause of African relapsing fever in man is a spirochete which is transmitted by the tick, *Ornithodoros moubata*, Murray.³⁴

In 1905, L. P. McCalla and H. A. Brereton transmitted spotted fever of the Rocky Mountains to man by means of tick bite (attachment) but their observations did not become generally known until they were published in 1908.

In 1906, W. W. King, and later in the same year, H. T. Ricketts transmitted spotted fever of the Rocky Mountains to guinea pigs.⁸³

With ticks proven to be a vector, and probably the sole vector of spotted fever, their important relation to that very fatal disease in the Bitter Root Valley of Montana became the

*Received for publication, September 2, 1931.

modulus for solving not only a very serious local health problem but a possible means for removing a very serious economic loss. The latter was entailed due to the justifiable fear of the disease entertained by old settlers and immigrants who refused to remain on the west side of the Bitter Root Valley. Thus hundreds of thousands of acres of exceptionally fertile land were kept from being settled and tilled uninterruptedly. The economic loss was so great that attempts at tick eradication in the Bitter Root Valley were anticipated as being profitable even at the expense of considerable experimentation and systematic, controlled efforts.⁶³

As a result, therefore, of economic pressure as well as humanitarian and public health considerations, there has been in Montana since 1911 a continuous scientific study and practical prosecution of tick control measures, with particular final reference to man, such as has never been attempted elsewhere. Thus, although we are indebted to veterinarians for the first studies directed at tick eradication, in its present day aspect we are almost entirely indebted to the Montana investigators and control officers for our current knowledge of the problems and methods involved in the control of the tick borne diseases.^{62, 63, 64}

Commenced initially with sole reference to spotted fever of the Rocky Mountains, the tick control program has become of constantly increasing significance in ratio with the number and importance of the several other diseases that have in recent years been demonstrated to be transmitted by

ticks, and to the evident widening dispersion of some if not all of them.

The diseases transmitted by ticks are spotted fever, tick paralysis, tularemia, American mountain tick-fever, certain indolent cutaneous ulcers of undetermined character, and, although apparently not in Montana or adjacent states, a relapsing fever of spirochetal origin.

Spotted fever, then considered to be cerebrospinal meningitis, was probably first described by Henry F. Hereford, M.D., of Gold Hill, Nevada, in Thomas M. Logan's article entitled "Report on the Medical Topography and Epidemic Diseases of California" published in the *Transactions of the American Medical Association* for 1866 (Vol. XVI, pp. 497-569). It was not however until the publications of Maxey, McCullough, Wilson and Chowning,⁶ Anderson, and Craig¹⁷ that it became known to investigators as well as local physicians.

Tick paralysis was first described by Seymour Hadwen from British Columbia in 1914.¹ It was first recognized as being of concern elsewhere (Idaho and Montana) in 1923 by James Dade, chief inspector of the Idaho State Sheep Commission. The disease has been subsequently studied by R. R. Parker and W. J. Butler.

Although *tularemia* was first shown (by the studies of 1910 to 1915) to be transmitted by the bite of the blood sucking deer fly, *Chrysops discalis*, it was later, in 1923, proven to be transmitted also by the wood tick, *Dermacentor andersoni*, according to demonstrations of R. R. Spencer and R. R. Parker.² The tick borne tularemia has also been studied by R. R. Parker, R. R. Spencer and Edward Francis.³

American mountain tick-fever was first described clinically in 1850 but without reference to being transmitted by ticks. Unaware of the earlier reports, Charles F. Kieffer in 1907 associated it with tick bites under the name of intermittent tick-fever. Since then it has attracted no notice except briefly in connection with spotted fever by F. E. Becker and by R. R. Parker, until the studies of the writer showed it to exist independently as a definite and distinct disease entity^{8, 9, 10}

The tick borne relapsing fever of spirochaetal origin, first reported from Africa, has a related form in parts of North America (Texas) and probably in Mexico, a known vector being the tick *Ornithodoros turicata*⁴

Thus there are in North America five well known specific diseases transmitted by ticks, and also certain indolent skin ulcers of unknown micro-gamic origin. But, as will be pointed out elsewhere, it is not to be supposed that a tick control (eradication) program of universal applicability can be worked out for all tick borne diseases and for all localities, as local circumstances and requirements differ very greatly, even radically. Hence each tick borne disease and tick infested locality will continue to have its own more or less peculiar problems, but whatever measures are successful in diminishing the incidence of a certain species, or family of ticks, will necessarily have some effectualness in reducing the prevalence of all the diseases transmitted by that species or group of species.

CONTROL MEASURES

Historically considered, tick control measures as related to the diseases

transmitted to man, had their inception in the general collective experience on the effect of avoiding certain localities at certain times of the year (avoiding exposure), and on the effect of the clearing of lands and of grazing, upon tick destruction⁸⁸

The above mentioned measures being found helpful but not sufficient the first studies in Montana were devoted to rodent destruction and the application of the well known dipping of live stock as had been practiced for many years in the control of the tick fever of cattle⁶⁷. The quarantining of stock, and the dragging for ticks were added, and rodent destruction became prosecuted in more ways⁸⁵. Lastly have been the introduction of tick parasites,¹⁷¹ and the use of a vaccine for one of the diseases (the Spencer-Parker vaccine for spotted fever)^{169, 190}

The measures will be studied systematically rather than in their order of introduction. It will be observed, however, that the two sequences coincide to a considerable extent. In this connection it must be remembered that it was almost from the outstart realized that no one or two methods alone were dependable but that optimum results were to be arrived at by finding the combination of procedures that gave the lowest infected tick incidence for the cost involved^{94, 95, 105}. The methods available will be considered in the following order:

Avoidance of Exposure

Hygiene (frequent inspection) of person
Periodical exodus

Tick Destruction

Clearing land
Grazing
Dragging
Dipping of live stock

Quarantining of live stock

Tick parasites

Rodent Control

Trapping

Shooting

Poisoning

Preventive Inoculation

Avoidance of exposure consists of systematic periodic search for ticks on the body and clothing of those who must enter infested districts, and the actual avoidance of infested areas during the tick season, the latter being from March 1 to July 15. Safety suggests, however, a removal out of infested districts from about February 15th to August 1st. The wearing of tick-proof clothing is helpful, but apt to be unbearable in summer time, and is at no time dependable, so should never lull the wearer into a false sense of security.

Where spotted fever is known to have a high mortality, periodical exodus of the rural population is still actually much practiced, but in the older control districts it is much less practiced than it used to be, and especially lately since the introduction of the spotted fever vaccine.

As to the conduct and value of these methods

Systematic periodical search for ticks on the body and clothing would be extremely valuable if carried out rigorously but the method is subject to the human elements of indifference, laziness and incompetence. Search should be thorough and at intervals not greater than twelve hours.

For thorough inspection individuals require assistance, hence it is best for groups to pair off so that each individual can have someone to act as assistant and inspector, this plan being additionally valuable in proportion to the mutual encouragement and

emulation it develops. The method is especially adapted for short camping trips and brief excursions into the mountains by trappers, range officers and lumbermen, but is often compromised by inadequate lighting facilities at night. Due to the human element, the method is impractical for prolonged periods, hence can not be included in a program devised for permanent residents. For health programs among tourists, campers and other casuals to infested districts, the twelve hour inspection and deticking method should be made the foundation of a prevention program. It has the advantage of placing no cost upon counties or the State, but does somewhat increase mental unrest. Periodical inspection is not of value against tularemia, American mountain tick-fever, the indolent ulcers, and spirochetal relapsing fever as a very brief period of attachment is sufficient to infect the individual with any one of those diseases, but for tick paralysis and spotted fever it is of value as attachment for about one and one-half hours is necessary for the tick to transmit spotted fever.

Detailed instructions concerning the character and arrangement of wearing apparel to diminish tick penetration, the habits of ticks, the preparation of camping grounds and sleeping arrangements, the search for and removal of ticks, and the treatment of tick bites has lately been published by R. R. Parker.²²⁴

Periodic exodus from infested districts during the tick season protects only for the time being and has no cumulative effect. It is economically expensive, but in dangerous uncontrolled districts it may be the only feasible method available.

Periodic exodus seems to have no appreciable effect in spreading ticks or the tick borne diseases, but it can not be denied that it has a slight tendency in that direction. It places virtually no direct expense on counties or the State but it does do so indirectly as it very noticeably depreciates business and the economic welfare of the areas affected. It contributes to mental unrest. Efforts should be made to make it unnecessary, and it should

not be part of an advertised program in a well controlled area, but as an emergency measure and for heavily infested areas that cannot economically support a control program the periodic exodus should not be discountenanced. During the period of exodus the method is of course effective for all of the tick borne diseases, but the method is, on an annual basis, not equally effective for all of the diseases as the mountain tick-fever, tularemia and perhaps tick paralysis are known to have a longer season than spotted fever, being not infrequently observed in August and occasionally in September.

We consider now the methods that largely comprise county or State control programs. They are methods that cannot for the most part be carried out effectually without county, State and even Federal assistance, coordination and control. They may be grouped under the headings of tick destruction, rodent extermination, and the use of prophylactic vaccination. All are necessary and economically justifiable for the most effective program in a thickly populated, heavily infested area but all are not equally available, economically, in thinly inhabited areas of low ground value.^{106, 116}

Tick Destruction

The clearing of land, especially in the more intensive types of farming, has a very marked effect in diminishing tick incidence but there is no reliable data as to what extent it does so. It has the unique advantage that it does not add an extra labor charge to the owners or tenants of farms, nor any additional cost to the county or State. It should be included as much as economic conditions warrant in any program for tick control.

Cattle grazing does not decrease tick incidence unless combined with dip-

ping. In fact without dipping it has some effect in increasing tick incidence and in spreading spotted fever.²¹¹ Combined with systematic and effective dipping it slightly decreases tick incidence.

Sheep grazing, at one time thought to be a valuable tick control measure,⁷⁹ has been shown to be of only limited value.⁸¹ It is chiefly of service on uplands, where it has a definite place in the program due to the lessened applicability of other methods in those places.⁸⁸

Dragging is a valuable method yielding quick results and particularly adapted for partially cleaning up small areas quickly. It does not have, however, sufficient cumulative effect to warrant a high labor charge. On the average, over a large project area the labor devoted to dragging should be kept to about one-fourth of that devoted to ground poisoning. It has the advantageous bi-effect of yielding thousands of ticks for experimental and other laboratory purposes such as the production of spotted fever vaccine.

The dipping of live stock is a useful method for tick control and yields results as quickly as dragging, but it also has no decided cumulative effect.⁹⁸ Granted proper facilities, the cost of dipping is not great compared to its value, but it has the disadvantage that it requires an appreciable capital outlay for dipping vats, and cannot in northern climates be invariably carried out as often as it should be, due to weather conditions. Dipping should be carried out preferably weekly, or at least every two weeks.

Dipping imposes some extra labor but farmers take to it readily provided the dipping vats are of convenient access. Beyond

the range of convenience there is noticeable indifference to dipping, the hand picking of ticks from cattle being more popular¹³⁷

Stock dipping can not be carried out as economically under semi-range and foot-hill conditions as where the area is entirely range land. However the dipping of live stock in infected areas has a definite place in tick control as it is available in foot-hill country where rodent control cannot be so successfully practiced. In those places wild animal life meets with domestic animal life and it naturally follows that dipping will do more good in such districts, although the amount of good it does in such districts is questionable²¹¹

The practice in Montana is to exempt milch cows from dipping provided the owner keeps them free from ticks by hand picking or by spraying with an arsenic-pine tar solution containing 0.22% arsenic trioxide

Dermacentor andersoni appears to be somewhat more resistant to arsenical dips than the cattle tick, and so it has been found best to add a soft soap-kerosene emulsion to the arsenical, following the Watkins-Pitchford formula⁵. By this addition the destructive effect of the material on the tick is increased and the caustic action on the host is reduced. This formula is as follows, English measure: Arsenite of soda (80 per cent arsenious oxide), 8.5 lbs., soft soap, 5.5 lbs., kerosene oil, 2 imperial gallons, water, 400 imperial gallons. It is important that the proper strength of the solution be maintained at all times, both to secure efficiency in tick destruction and to avoid injury to the stock⁶. A simple outfit has been devised by the U. S. Bureau of Animal Industry for determining the percentage of arsenic present⁷.

The quarantining of stock during the tick season does not reduce the incidence of ticks in the infested areas. The measure was introduced to prevent the mechanical carrying away of ticks from dangerous areas, in that respect it is undoubtedly very successful. Animals that must be shipped during the tick season are released from quar-

antine only after being dipped and inspected by a state officer for freedom from ticks^{137, 211}

The cost of enforcing quarantine is nil or very trifling as the duty of enforcing it is merged with the duties of the brand inspectors.

Tick Parasites

The high mountain reaches being the fountain head and impregnable fortress of both ticks and wild animal life, they are unassailable by the control measures already mentioned, including the rodent control measures to be mentioned. Hence a new method is necessary that will offer some prospects of destroying ticks above the foot-hills¹⁸³. In hopes that they might find the ticks in their inaccessible abodes, the tick parasite, *Ixodiphagus caucurtei* du Buysson, a minute chalcid fly was imported into America from France in 1926¹⁸⁴.

A great deal of work has been done by Cooley, Morton and Kohls on studying the tick parasite, *Ixodiphagus caucurtei*, with particular reference to its artificial propagation,¹⁸⁵ its suitability for the climate of Montana, and its liberation at strategic points¹⁸⁶.

The chalcidoid fly has been reared in large quantities by the Montana State Board of Entomology in its laboratory at Hamilton, Montana. These minute flies have been liberated to the extent of about two million specimens during the past four years (1927 to 1931). Twelve colonization areas have been selected in western Montana and seven in eastern Montana. In 1929, one year after the release of 82,200, in the Lick Creek area, 250 engorged nymphal ticks were secured from 108 squirrels. Upon incubation it was found that 14 (7.5 per cent) of the ticks were parasitized. Equally encouraging results were not obtained in 1930, but the data obtained were too limited¹⁸⁷.

warrant the drawing of conclusions. Although it is much too early to determine what will be the ultimate value and results of tick parasite liberations it may be said that all theoretical considerations and practical observations are distinctly encouraging at the present time. Obviously it is impossible to equate cost with results at this time but the work being done along the line of tick parasites has the very great advantage that it is constructive and cumulative in value, and is available in regions where other methods of tick control are not available.

Rodent Extermination

The shooting of rodents should be encouraged by permitting an open season at all times as far as rodents are concerned. Shooting does not, however, sufficiently reduce the incidence to warrant the paying of a bounty unless of a very trifling character. It should be an incidental but not a main effort of county and state employees as it is not sufficiently productive of permanent results to justify the cost of time and material required.

Trapping, likewise, should be a method available to the public at all times, and one employed by control officers incidentally to other field work. It does not kill enough immature animals to have much cumulative effect, hence does not warrant a high labor cost or the paying of more than trifling bounties.

Shooting and trapping are of most value for clearing up very small areas for brief periods, and are of chief applicability for certain points with a brief tourist season.

Rodent extermination by means of poison has the most cumulative effect as it kills the fair proportion of immature animals before they have opportunity to breed. It is not, however, as productive of quick results as are shooting and trapping. Poisoning of

lands can not be carried out discursively for best results but should be carried out in a planned and systematic manner, extending concentrically from strategic points. The use of poison is especially adapted to plains and low foot-hill areas but is not feasible for mountain sides. The poison placed on or near grazing lands occasionally kills live stock as well as rodents, hence farmers are at first usually actively opposed to its use. It can be shown, however, that the loss entailed is comparatively trifling. Where there are means for compensating farmers for their loss, opposition to rodent control by means of poison becomes less in time as eventually the farmers' live stock is considerably improved by being kept free from ticks.

The Montana experience has been that of 41 cases of stock poisoning reported in the seven years 1923 to 1930 (over an area of about 425 square miles) investigation resulted in a settlement being made in 20 (about one-half) of the cases. The average per annum cost of settlement for the five years 1924 to 1929 was \$120, and represented the loss of six horses, eight cows, nine pigs, nine sheep, and four geese for the five-year period, or about three large and four small animals per year. The above low loss of stock and cost to the State could not have been accomplished, however, without experienced labor in placing the poison and without careful investigation of claims (including toxicologic analysis of viscera of allegedly poisoned animals). Since strychnine has lately been replaced by calcium cyanide under certain circumstances, the loss of live stock will be still less ^{170, 180}

The effect of the systematic annual and partly semi-annual use of poison in the Hamilton to Missoula, Florence, and Lolo districts of Montana has been to reduce the rodent population as observed on a measured trip (at the same time of the year) from 194 in 1924 to 16 in 1930.

The cost (time and material only) of rodent control by poison has averaged \$0 02681 per acre per year for the four year period 1927 to 1931. This is equivalent to a cost of \$5 362 per year for a 200 acre farm, or \$26 81 for a five year period. After the latter has been established the control by poison can be maintained for about \$5 00 per year, or \$2 50 per 100 acres if done intelligently, systematically and on a large enough scale.

The combined amount of land treated in the Ravalli County and Missoula County control areas in 1927 was 246,697 acres and in 1930, 271,533 acres. The latter is equivalent to about 425 square miles or a strip eight miles wide by 53 1 miles long. The average total annual cost for the area was \$7,280, representing a labor of 1,456 eight-hour days or the employment of sixteen men for ninety-one days a year. The average number of baits per acre were 4 02 for Ravalli County and 1 22 for Missoula County. A trifle over one-third of the land was poisoned twice a year. The amount of materials used in 1930 were 6,686 quarts of poisoned grain and 5,261 pounds of calcium cyanide.

The poisoned grain is made by mixing crushed whole oats, 40 quarts, with a solution of molasses (4 pints of molasses and one and one-half quarts of water) in which has been dissolved a mixture of strychnine, 5 ounces, saccharine, 5 drams, gloss starch, 2 5 lbs., and sodium bicarbonate, 5 ounces. The dry powders are first mixed together and then dissolved in the warmed solution of molasses. The whole is then poured over the oats and rapidly mixed by hand. Rubber gloves should invariably be worn and the hands thoroughly washed after mixing the poison into the grain. The grain-poison mixture is then spread on canvas or muslin racks until it is thoroughly dry.

About one teaspoonful is placed usually on the surface of the ground at the rear of the rodent's hole or burrow. It should be either spread out over the ground or placed in a small shallow depression where it will be accessible to the rodents but not attract the attention of large domestic animals.

Prophylactic Vaccination

Recognizing that tick eradictory methods and rodent control measures

were but partially successful at best, even when intensively practiced, and that no method except the frequent periodic inspection of the body for ticks was available against spotted fever in areas beyond the controlled areas, the desirability of artificially immunizing people against spotted fever was at once apparent. Accordingly, R. R. Spencer and R. R. Parker at the Montana Laboratory for the Study of Insect-Borne Disease, Hamilton, Montana, developed a vaccine of considerable protective value against spotted fever. The vaccine is prepared solely by the U. S. Public Health Service at Hamilton, Montana.

At present spotted fever is the only tick borne disease for which there is a method of prophylaxis by means of inoculation.

The vaccine for active immunization against spotted fever is of the attenuated virus type. It is to be used before the tick season in two doses with a week's interval between doses. It should be repeated annually. The annual inoculations seem to have a slight cumulative effect.

About twenty-five thousand persons have been inoculated with the vaccine during the period 1925 to 1931 inclusive. Each year there has been an increasing demand for the vaccine and it has been necessary to increase production accordingly. The amount manufactured was doubled in 1929, again in 1930, and again in 1931. The heaviest call is from Montana, Wyoming, Idaho, and Oregon, the last named state using the most in 1930.

From the results of a two year test (1926 and 1927) made in southern Idaho against the mildest type of the disease and another test against the most virulent type, which had been in progress for four years in the Bitter Root Valley, the following conclusions were expressed—that against the milder type of

infection the vaccine usually afforded full or nearly full protection, while against the highly virulent type the degree of protection was usually sufficient to cause a marked amelioration of the customary very severe symptoms and to insure the recovery of most cases. No further test was deemed necessary so far as the mild types were concerned, but additional data seemed desirable in regard to efficacy against the virulent type. Therefore, complete record keeping in the Bitter Root Valley has been continued. The full six years' data for this valley (1925 to 1931) show that since the beginning of the test 3,578 persons have been vaccinated, of which nine have received vaccine in six different years, 64 in five years, 143 in four years, 257 in three years, 555 in two years, and 2,550 once. During this test period 46 persons have become infected with the highly fatal local strains. Of these, 30 were in non-vaccinated persons and 16 among those vaccinated. Of the 30 nonvaccinated cases, 22 died, of the 16 vaccinated only three. The death rate in the former group was 73.33, in the latter 18.75, thus showing a marked reduction in mortality in favor of the vaccinated cases.²⁰⁰

The cost of manufacture of the vaccine has been thought to make its manufacture commercially infeasible. While this fact was undoubtedly true in the experimental stage, there seems reason to suppose that with demonstrated value, and larger production, the manufacture can now be put on a commercially justifiable basis.

COMPARATIVE ECONOMICS

Total economics cannot be given accurately at the present time as a true pro rata cost of the tick parasite efforts and the prophylactic vaccination campaigns cannot be more than approximated.

Of known costs, rodent control by poisoning of land places an average charge of \$5 per 200 acres, dragging about one-fourth as much again, dipping about one-half as much again and general overhead and administration

charges for these control measures, an additional one-fourth so that the annual charge for these measures is about \$10.00 per 200 acres (or average farm family), the per capita cost being about \$2 per year. Assuming vaccination to be on a commercial basis it could under average conditions be carried out on a cost basis for about one dollar a year for urban inhabitants and two dollars a year for rural inhabitants, assuming organized effort and full cooperation of the inhabitants in reporting to conveniently placed temporary stations (physicians' offices, public health booths, etc.).

Thus for all tick and spotted fever control measures other than the tick parasite investigations there is in heavily infested but well controlled areas an annual cost (averaging rural with urban) of about \$3.50 per capita or \$17.50 per average family on a 200 acre farm or \$8.75 per 100 acres. General research work would bring this up to \$10.00 per 100 acres per year. Compared with many other reclamation projects (drainage districts, irrigation districts, etc.) this is not an economically unjustifiable charge for land of good average productivity, although it must be remembered that it is not a temporary charge for a permanent or semi-permanent improvement but is an indefinitely necessary annual charge with only slight to moderate cumulative effect, and none that would endure more than briefly if all control efforts were relaxed.

The above costs are obtained under reasonably favorable conditions. Under but slightly less favorable conditions they might be two, three, or four times as great. Hence, unless land is of ex-

ceptional economic value it can not afford to carry the burden of much control work of present type spent on difficultly controlled adjacent uplands of low economic value. Also, it should be remembered that initial efforts are always more expensive than subsequent maintenance efforts. Hence an initial three to five year tick control program would have to provide an average annual charge of perhaps \$12 to \$14 per 100 acres, and under some conditions (transportation facilities, etc.) even more. Mountain sides and other timber land obviously cannot bear one-tenth such a cost, and yet they are the fountain head, and so far unassailable fortress, of tick life. It is on account of these considerations that efforts towards propagating tick parasites are so very important. On the other hand, if an individual can be effectively immunized against a tick borne disease, the concern as to tick incidence is proportionately reduced, at least as far as that disease is concerned.

Where dangerously infected areas have a recreational appeal of a dispersive sort it should be the policy of the responsible control officer of the area to close certain parts of the dangerous area to the public, which will thereby concentrate recreational activities in a locality or localities that can be controlled with fair prospects and economic justification.

RESULTS OF TICK CONTROL MEASURES AS TO REDUCING MORBIDITY IN MAN

Tick control measures have decided value in relation to improving animal husbandry (tularemia, tick paralysis, etc.) and these valuable by-effects should be kept in mind. The purpose

of this article is, however, to consider only the demonstrated effect of tick control measures in reducing disease in man.

Spotted fever as existing in the Bitter Root Valley affords a valuable yardstick on account of the reliable statistics that have accumulated on the subject during the past thirty years.

From 1913 to 1929 there were 113 cases of spotted fever in Missoula, Ravalli and Granite Counties (the Bitter Root Valley) Montana. Of these, 48 cases (42.5 per cent) occurred in the older control districts of the Florence, Stevensville, Victor, Hamilton and Gold Creek areas, all in Ravalli county.^{21,2} In these areas combined, the following number of cases occurred

In 1913 and 1914	14
1915 and 1916	7
1917 and 1918	0*
1919 and 1920	5*
1921 and 1922	8
1923 and 1924	6
1925 and 1926	3
1927 and 1928	2
1929 and 1930	1

*The reduction in these years was very probably largely due to the diminished male population on account of the men being away in army service during the World War.

Comparing the quadrennium 1913-1916 with its 21 cases against the quadrennium 1927-1930 with its 6 cases we find a reduction of morbidity in these areas from 100 per cent to 28.6 per cent (actually the reduction was to under 25 per cent of the old uncontrolled rate, as the first four years, 1913-1916, showed some effect of tick control measures).

On the same basis, for the whole valley the reduction would be from 38 cases in 1913-1916 to 10.87 cases in

1927-1930, or 27 cases less during a four year period. As the death rate for all unvaccinated cases in this valley has for thirty years been 76.81 per cent, it is safe to say that of the 27.13 fewer cases, 20.84 cases (76.81 per cent) represent lives saved, or a trifle better than five a year. Placing for economic purposes a nominal value of \$2,500 per average human life, this would represent a saving of \$13,000 a year, which with \$2,000 for critical illness and temporary loss of earning power, for six others, would in an economic way well balance the total known cost of control measures, which was on the average of ten cents per acre for an average of about 150,000 acres (well under that number before 1927, up to 271,500 since then) or about \$15,000 a year.

While these figures do not represent any "juggling" it is not to be understood that they are meant to represent more than an *approximate* appraisal of economic results. At that, however, they do indicate that even on a crass economic basis it is evident that all moneys spent for tick control measures have been spent justifiably, on a human morbidity-mortality basis alone.

In addition there has been, besides improvement in quality of live stock, an enhancement in land values that alone would have more than justified the cost of all tick control measures. Thus it is safe to say that over an eighteen year period of tick control, the fundamental land values of the Bitter Root Valley have appreciated at a rate greater than an annual average of \$50,000.

To the known savings effected in connection with spotted fever should be added the diminished incidence of the other tick borne diseases. The amount of diminution of the latter is not known, as only recently have tularemia and tick paralysis been recognized in man, and the American mountain tick-fever has not attracted attention in the Bitter Root Valley in recent years. As already remarked, the distribution of the tick borne diseases varies somewhat according to locality, hence a tick reduction program elsewhere might not be as economically productive of good as it has been in the Bitter Root Valley, even though the other tick borne diseases were almost totally eliminated, as collectively they do not seem to be of an economic importance equal to that of spotted fever.

The Etiology of Colds*

By JOHN E. WALKER, M.D., *Opelika, Alabama*

THERE is a growing conviction that colds are due to a specific filtrable virus. This conclusion is of such importance that the evidence leading up to it needs to be examined critically. The evidence in favor of the view is two-fold. First, experiments have been reported which appear to show that colds can be transmitted to humans and to chimpanzees by bacteria-free filtrates of nasopharyngeal secretion obtained from persons suffering from colds. Secondly, it is supposed that there is sufficient evidence to show that ordinary bacteria, while admitted to be pathogenic, are in no way concerned in the primary etiology of colds. It is the purpose of this paper to consider the nature of this dual evidence.

TRANSMISSION EXPERIMENTS WITH FILTRATES

The experimental method relating to the transmission of colds with bacteria-free filtrates of nasopharyngeal secretions is simple in principle. The filtrate is instilled into the nasopharyngeal passages of volunteers who are kept under observation to determine whether or not they develop a cold. The interpretation of results however is full of pitfalls, for there are no cri-

teria of successful transmission other than clinical symptoms. These clinical symptoms are very indefinite both in kind and in degree. Anything between a transient nasal discharge and pneumonia may be so classified, possibly correctly so far as we know at present. No one would attempt to define the severity of headache, the amount of sneezing, the degree of hyperemia of the mucous membranes, the severity of sore throat, or the volume of nasopharyngeal secretion necessary to establish the diagnosis of a cold, or even to say which of these symptoms need be present. Yet, it is solely on such symptoms that the interpretation of transmission experiments depends. Experimenters cannot protect against error by disregarding mild symptoms, this recourse would still leave the etiology of mild colds unsolved.

Further, suggestion plays a great part in the subjective (possibly also the objective) symptoms of the volunteers. Only those who have served as subjects for such experiments, as I have done, know fully the potent influence of this factor. The curiosity and expectation are intense, every breath is carefully drawn in to detect possible nasal obstruction; every sneeze is followed by an anxious waiting period for other sneezes.

Dochez¹ and his co-workers found

*Received for publication, November 20, 1931

this factor of suggestion so powerful that it was necessary to use "various ruses, such as nasal injections of sterile broth, collection of nasal washings for culture and equivocal statements" in order to keep the subjects in ignorance. One of their subjects in particular appeared willing to develop or not to develop a cold according to what he thought was expected of him. Also, he was willing and anxious to change his symptoms if he thought that his first impression was an error. In view of these considerations, and the well known tendency of humans to develop respiratory symptoms at any time, it is extremely doubtful whether such symptoms¹ as a mild cold "in which sore throat, laryngitis and cough with a moderate amount of sputum were conspicuous" or "a simple uncomplicated mild cold" can be given sufficient weight on which to form a final judgment. This is particularly the case, since no volunteers submitted to the same psychic influences were reserved as controls.

Long² and his group also recognized the possibility of error as a result of the psychic reactions of the subjects. During a five day period the subjects were given several nasal instillations of broth in order to keep them in ignorance. Yet, at the end of this time, they all received instillations of filtered nasopharyngeal secretions. The control group was the general population of Baltimore, persons living under entirely different conditions, not elaborately hospitalized like the volunteers, and certainly not subjected to "careful examinations of the nose and throat by several observers" as soon as they complained of symptoms.

Besides the factor of suggestion, the interpretation of symptoms following the nasal instillation of filtrates is rendered all the more difficult since, as stated by Dochez,¹ the filtrates are irritating to the mucous membranes and cause in "practically all cases, negative and positive, some slight stuffiness of the nose, a little sneezing, and occasionally slight headache." This is further complicated by the fact that the subjects received intranasal instillations of broth, likewise irritating, in the days immediately preceding the test inoculations. No one apparently has attempted to determine the effect of this repeated instillation of irritating liquids on nasal symptoms in humans. The powerful effect of irritating chemicals in causing nasal symptoms in rabbits was shown by Carrol G. Bull.

The great importance of this subject for human welfare requires that such experiments be better controlled. Larger groups should be used, say 50 to 100, with an equally large control group. It is obviously unnecessary to hospitalize these persons if they are kept under the same living conditions. Preliminary broth injections are also unnecessary in an adequately controlled experiment. However, the subjects and also the observers responsible for the diagnosis of colds should be in complete ignorance as to the nature of the instillations used. I know of no place where such an experiment could be satisfactorily performed outside of the military service.

Unfortunately, such an experiment even with a markedly significant difference between experimental and control groups would not settle the problem by proving that colds are due to a filter-

able virus There is another objection to be answered Filtered nasopharyngeal secretions contain a number of substances in solution, substances derived from micro-organisms as well as of human origin It is more than a theoretical possibility that the coryzas following the nasal instillation of such substances represent an allergic response by the nasal mucous membrane There is no more reason to consider the coryzas produced by such instillations as due to a filtrable virus than there is to consider the ophthalmic reaction following the instillation of minute traces of tuberculin as due to a filtrable virus The nasal mucosa is more apt to respond to foreign substances by allergic reactions than any other tissue of the body The absence of a specific skin reaction to the nasopharyngeal filtrates would not influence the question These views regarding the possible allergic nature of the coryzas following the nasal instillations of filtered nasopharyngeal secretions were expressed ten years ago by Victor C Vaughan,³ though as far as I can determine none of the proponents of the filtrable virus theory has made any effort whatever to take them into consideration

Experiments⁴ have been recently reported regarding the possible cultivation of this hypothetical virus It is to be noted that the authors were properly conservative in their claims saying "we realize the difficulty of a final judgment concerning the successful cultivation of an invisible agent and simply present the facts as we have observed them" The experimental method was, of course, exactly the same as that discussed above, the only difference being that here the "virus" was obtained

from a test-tube instead of directly from the nasopharynx The same objections regarding interpretation likewise apply

In short, the filtrable virus theory of colds is not only unproved, but even if correct, it appears impossible to prove it with the means at present at our disposal

THE HYPOTHESIS THAT COLDS ARE NOT DUE TO ORDINARY BACTERIA

Another series of experiments by Shibley,⁵ Hangar, and Dochez, is commonly cited as demonstrating that bacteria can no longer be considered of importance in the primary etiology of colds In these experiments normal individuals were studied over a long period, and changes occurring in the respiratory flora during the development of colds were noted The authors⁶ state that "from the results of this study we were led to conclude that none of the aerobic organisms is of primary etiologic significance because none appears for the first time in significantly increased numbers during the early days of a cold Later they may be present as important secondary invaders" But lateness of appearance of an organism in artificial culture does not *ipso facto* displace the organism from the position of primary etiology This point can be demonstrated by reference to two observations that have been made by me

1 A *culture* of *B. Pfeifferi* was accidentally sprayed over the face of a laboratory worker A severe upper respiratory infection followed, characterized by watery nasal secretion, bronchitis and conjunctivitis Late cultures made from the exudates showed myr-

iads of organisms serologically identical with the organism inoculated. These positive late cultures contrasted strongly with the fact that an early culture made, however, at a time when symptoms were well established, was entirely negative for this organism. This observation is in many respects similar to a spontaneous cold recorded (Case 1, K C M) by Shibley⁵ and his co-workers and on which their conclusion already referred to was partly based. K C M showed no Pfeiffer's bacilli on nasal culture when symptoms first appeared. Later nasal culture showed a pure growth of this organism. Most probably K C M's cold was caused by *B. Pfeifferi*, exactly as there is no reason to doubt that this organism was responsible for the infection recorded by me.

2. A⁸ dilute culture of *Micrococcus catarrhalis* was purposely inoculated into the nose. A cold characterized by watery nasal secretion, sneezing, and later mucoid nasal secretion followed. Cultures of the mucoid nasal secretion showed many colonies of *M. catarrhalis*, although a previous culture of the early watery secretion had been entirely negative for this organism. I was the subject myself for these two observations. I make no claim of absolute freedom from disturbing psychic reactions. However, the inoculation of cultivatable bacteria and the later recovery of these bacteria by culture are concrete facts, for which there is no parallel in filtrable virus experiments.

It is not surprising that the thin watery secretion which often characterizes the early stages of a cold should contain few or no organisms. The situation is probably similar to that in

which only a few pollen granules are necessary to produce an attack of hay fever. No one, of course, would contend that the extrinsic factor in hay fever is not pollen merely because pollen cannot be demonstrated in the nasal discharge. Nor would anyone consider that hay fever was due to a virus if it should be demonstrated that the filtered nasopharyngeal secretion of one victim caused symptoms when instilled into the nasal cavity of another susceptible person. The mechanism of colds is possibly very similar to the mechanism of hay fever, with the exception that the causative agent in the case of colds is capable of multiplication, of actual invasion of the tissues, and of giving rise to a purulent exudate in some instances.

The experiments with chimpanzees, reported by Dochez¹ and his co-workers, also bear certain points of resemblance to the two observations made by me. These animals were inoculated with filtered nasopharyngeal secretions, and seven of sixteen animals so inoculated developed colds. This observation is cited by Dochez as further evidence supporting the filtrable virus hypothesis. But the animals developing colds showed a great increase in pneumococci or *B. Pfeifferi* on culture of the nose and throat as the colds progressed. I feel that it is much more logical to attribute the colds to these organisms rather than to postulate a virus in the filtrates. An adventitious origin of the colds cannot be excluded, particularly since these animals are very susceptible to such infections. Although eight control animals did not develop colds, it is to be noted that the work with the controls was done in June and July.⁹

while the filtrates were inoculated in the test animals in winter. Obviously, the controls are not strictly parallel. Further, as in the case of the human experiments with filtrates, the possibility of an irritating or allergic reaction caused by the filtrates and paving the way for later bacterial invasion was not taken into consideration.

A great lacuna in this work with chimpanzees is that none of them has been inoculated with ordinary respiratory bacteria. My own experience with laboratory infections due to respiratory bacteria convinces me that the resulting cold may be too cruel and too severe for any widespread use of human beings for this purpose. It appears permissible, however, to inoculate humans with diphtheroids and *M. catarrhalis*, preferably such organisms as have not had many generations on artificial media.

The two observations mentioned above relating to the development of colds in humans following the intranasal inoculation by no means exhausts all instances of this kind. I have recorded a second infection due to *M. catarrhalis*, and still another¹⁰ resulting from *B. bronchisepticus*. I was also the subject of these experiments. But the literature is replete with other examples cited, among others, by Park and Cooper,¹¹ by Cecil and Steffen,¹² and by Fenyvessy and Kopp.¹³ In the presence of this mass of evidence it seems unjustified to conclude that we need no longer concern ourselves with the possibility that ordinary bacteria may be the primary etiological agents of colds.

SUMMARY

The reported experiments relating to the hypothesis that colds are due to a filtrable virus are inadequate to support the hypothesis. Such disturbing factors as difficulty in diagnosis, the influence of suggestion on the subjects, the irritative properties of the filtrates on the nasal mucosa, and the possible presence of allergic reactions to the filtrates have not been properly controlled. With the means at present at our disposal it is even doubtful whether the hypothesis can be submitted to proper experimental test.

The filtrable virus hypothesis rests on another hypothesis, namely, that ordinary respiratory bacteria are not concerned in the primary etiology of colds. This underlying hypothesis is likewise unproved. Two personal observations are cited which demonstrate that causative bacteria may be absent in early cultures made from the exudate in colds. These, and other instances from the literature, favor bacteria as being the extrinsic factor in the etiology of colds.

The early reaction in colds is probably very similar to the hay fever reaction to pollens. The difference consists in the fact that the etiological agent of colds (bacteria) possesses the power of multiplication and of tissue invasion. Later they may give rise to a purulent exudate. The etiological agent may be very numerous in culture only in this purulent exudate. The late appearance of bacteria in cultures does not prove that they are merely secondary invaders.

A Layman Considers Migraine*

By WALTER B. SHEPPARD, *Denver, Colorado*

ALAYMAN, who has been subject to migraine for forty-seven years, who is quite familiar with its voluminous literature, and who is fairly well versed in what little is known about the human metabolism, may possibly have made some observations worthy of notice by the medical fraternity

ETIOLOGY

Migraine is not an ache, but an acute pain, typically localized above and posterior to the supra-orbital process, but it may rarely be parietal or occipital, and it may switch its site in different attacks or in the same attack. It is a distinct pathological entity, always inherited, though in transmission it is not always true to type, and the heredity may thus be obscured. It usually

begins in childhood or adolescence, seldom after 19. The precise nature and basic causation of the disorder are still shrouded in mystery. No explanation fits. Every theory is shattered by some specific incompatible clinical fact. Anything that lowers a patient's threshold of resistance may precipitate a seizure,—may pull the trigger, so to speak,—but what loads the gun is wholly unknown.

While the disorder is incurable, and is prone to increase in severity and frequency, it tends often to remit, in women more or less abruptly at the menopause, and in men to taper off with the gradual subsidence of gonadal activity, but many sufferers find relief in the grave alone. These spontaneous recoveries would seem to impose a complete negative on all attempted etiologies, including the latest candidacy, sensitization.

*Received for publication, February 19, 1932

NOTE BY EDITOR The author of this paper is now 66 years of age. He believes that he inherited his tendency to migraine from his mother. It first appeared when he was in college at the age of 19. He has been an editor, but so severe and so frequent have been his attacks of migraine that he dare allow himself but two or three hours of close mental application a day. He has read extensively of migraine and has experimented with himself for nearly a half-century. The record of his observations and his conclusions cannot but be of interest and value to professional readers.

There does not appear to be much valid evidence going to show that migraine's relation to allergy is anything but fortuitous or coincidental. Out of 441 perennial hay-fever cases studied by Balyeat, 17 only, or 3.8 per cent, presented the migraine complication, although more than 50 per cent, all told, had some other indisputable allergic reaction, such as asthma, urticaria, or eczema. The fact is, in the early years of migraine, almost any

medical intervention, or improvement in regimen, or removal of some proximate cause, such as dietary indiscretion, eye-strain, constipation, or the like, may effect a "cure", which is not permanent

Possibly the most plausible explanation of the migraine complex, as yet totally unsubstantiated, is to ascribe it to some specific metabolic or endocrine idiosyncrasy. It is apparently not easy to account otherwise for the spontaneous recoveries, which occur, if at all, almost invariably in the last decades of life. That failing gonadal function, or any concomitant of the same, can have any causal relation to anaphylaxis, is a tax on credulity. In common with all forms of life, mankind universally in senescence or sooner becomes sexually impotent. But migraine may persist till the end of life, even to the seventh or the eighth decade. It is in the later decades that resistance to anaphylactic shock should, *a priori*, be at its lowest ebb. In theory, therefore, if allergic in origin, migraine should never be "cured", in the latter end of life. In truth, however, recoveries almost never occur at any other time, while the true allergic disorders evince no disposition to cease at this period.

There would seem to be some color for the suspicion that the spontaneous recoveries are related to a diminishing or suspended supply of some unknown hormone or catalyst, that has, earlier in life, been thrown into the bloodstream in excess, or of faulty quality. This notion is not in conflict with the invariable tendency of all glands, unless it be the prostate, to subinvolute in later years, and with the fact that func-

tional and anatomical abnormalities are prone to be transmitted.

PRODROMES IN MIGRAINE

For a day or more before the attack, the patient is likely to be jerky and irritable, his muscles may twitch, especially those of his face and eyelids, and at night he may be wakened by the frequent involuntary contraction of legs and arms, as well as by the itching of his skin about the nose and mouth. Sleep has been broken and unrestful, partaking of the twilight variety, though on the night immediately preceding the attack, it may have been "druggy". While the seizure is brewing, there is apt to be a ravenous appetite, accompanied by a pronounced sensation of tension in the abdominal viscera, together with borborygmus. There has been, the day before the onset, an unusual subjective feeling of complacency and competence. If there was shock, mental or physical, it entailed an excitation, closely resembling that induced by an overdose of caffeine, the patient can not "let down", or stop the pounding of his heart, or make his mind behave, a torrent of thoughts and images pours through his brain for hours,—and the state is apparently objective wholly, due perhaps to some disturbance of the endocrine balance.

The actual onset may begin at any hour, but it most often occurs in the morning, after some stress or imprudence of the day previous. It is often ushered in by a slight dull ache through or above the eyes, at this stage indistinguishable from the mild negligible aches caused by or accompanying constipation, eyestrain, fatigue, hyper-

chlorhydria, scanty ingestion of fluids, and the like

While the day before, the patient felt equal to almost anything, this morning he is lethargic, inert, and equal to almost nothing. He lacks appetite, and his food does not taste right, his vision is changed, and his lenses, if he wears any, do not fit, owing to distortion of the eyeball. Feet and hands are cold and clammy.

The prodromal stage may not be very noticeable, and may last for days before the actual onset, and may even be aborted by purgation, especially early in life, or an attack may be precipitated by some trifle. Or the symptoms may subside without medication. Beginners, whose seizures occur infrequently, can almost always stave off any individual attack by prompt and vigorous catharsis, by a saline or aloin, if exhibited on the first appearance of the characteristic prodromes, which every patient soon learns to distinguish almost unerringly.

SYMPTOMATOLOGY

At the outset, migraine may occur not oftener than once or twice a year, or even less frequently, later as often as twice a week. In truth, in severe types, reckless indiscretions are fully capable of inducing repeated seizures, one after another, so close together as to be practically continuous. Early in life the attack may be slept off, or may end with emesis, later, the duration may be so long as a week or more. When the habit has been fully established, two or three days, in the absence of medical intervention, are about the average. The characteristic pain may be a by-product, for the custom-

ary concomitant metabolic disturbance may endure for days after the pain has ceased.

Scotoma may usher in an attack, but either may be present without the other. Periodicity, except in women at the menses, is not marked. Long-standing cases take no account of periods. Pain and the metabolic explosion may be so severe and prolonged as to induce symptoms of traumatism. Toxemia may be so profound as to resemble uremia in all respects except casts and albumin. Exceptionally heavy visitations may be accompanied by arthritic symptoms in maxillary and neck muscles, on the same side as that on which the pain is localized, and this pseudo-arthritis may last for weeks.

There is often a drop in bodily temperature, even to 95° or less, and a rise in systolic pressure, but neither manifestation is invariable, during attacks. There is nearly always more or less pneumogastric disturbance, as evidenced by dyspnea, arrhythmia, excess secretion of saliva and of nasal mucus. As in gout, there is apt to be polyuria before seizures, but during the attack, the urine, as in gout, is pretty sure to be scanty and heavily charged with solids. Peristalsis is usually diminished before and during the attack, but migraine may occur during diarrhea or catharsis.

The tongue is usually, but may not be, furred; a blackish tinge is an index of the severity of the visitation. During seizure, the temporal arteries may be much distended, while the distal arterioles are constricted, but marked vascular change may be absent. It is possible that the pain may be caused by a vasomotor disturbance in the cerebral

cortex, as has been postulated, but there is no clinical evidence going to establish the validity of this theory and that edema could occur hundreds or thousands of times in the same area, with no resultant structural change, or mental impairment, is hard to believe.

Before the actual onset, there may be marked mental depression, and during, before and after, considerable hebétude. The patient does not lose his zeal, but regardless of pain and malaise, he is able to do very little. His mind refuses to do his bidding, he feels as if drugged, he can not recall names, or remember what he reads or hears, he misuses words, has difficulty even with his wonted daily routine, can not trust himself to compose a business letter, all his sense-perceptions are more or less obfuscated, especially sight, hearing, and taste.

While nausea is common, emesis is often impossible, so that undigested food may remain in the stomach during most or all of the attack. There is probably always hyperchlorhydria, caused perhaps by hepatic congestion, and the excess of acid may abrade the stomach mucosa, so that eructations are streaked with blood. Even if or when emesis is induced, the stomach may continue to "buck" for hours after it is emptied, even water may not be retained. Heart action is usually slowed down, even to 50 per minute, and the radial arteries are usually threadlike. Tenderness of scalp, at the seat of pain, is common, and there may be desquamation at the same site.

Early in life, any individual attack is likely to end abruptly, after vomiting, or purgation, later, remissions are usually gradual, extending over hours

or even a day or more. As a rule, sleep is difficult to compass, during attacks, regardless of pain. Loss of sleep, together with exhaustion from pain, may induce between attacks and during them an added constant headache of neurasthenia. Thus the patient, unless or until he capitulates in some degree, may be reduced to helplessness.

The onset of migraine is usually not sharply defined, most often it travels with a leaden heel. The pain is apt to begin diffusely through the eyeballs, or frontally, over the brows, but it soon localizes, and is justified of its name, hemicrania. With actual advent, the patient's feeling of tension may abate, but this may be partly auto-suggestion, for this pathology inculcates resignation, at least after thirty or forty years of suffering. In that migraine is essentially a toxemia, it is rather odd that it does not seem to shorten life or impair mentality. On the contrary, its victims are not below the average in acumen or longevity. Trudeau told this writer that possession of this complex seemed to inure to the advantage of those with pulmonary tuberculosis. And it is a fact, that any intercurrent infection with pyrexia will result in complete freedom from migraine for weeks or months. But any vicissitude, as prolonged convalescence from severe illness, or traumatism, may be followed by marked and lasting exacerbation of the migraine.

PROPHYLAXIS IN MIGRAINE

In that migraine is incurable, intervention would seem especially indicated along the lines of prophylaxis. Anatomical abnormalities impairing function should be removed, defective vision

aided with proper lenses, practices that lower body tone discarded. But after all has been done, the patient still has his migraine. At most, the sphere of his activity may have been widened somewhat for a time. But, as he is usually ambitious and unable to achieve a vegetable existence, he is apt to transcend his limitations as much as before, so that the net result, so far as the migraine is concerned, is pretty sure to be nearly nil.

It is not possible to devise a regimen for every individual case. Prophylactic expedients are many and varied, and should include. A maximum allowance of sleep, a minimum of stress, mental or physical, a diet carefully regulated, both as to quantity, quality, and components, an active elimination.

Migraine being a toxemia, its victims have much to oxidize. By reason of over-acting adrenals, hepatic and thyroid efficiency is constantly impaired, and peristalsis slowed down, while pancreatic activity is diminished. That is, metabolic instability is accentuated at the very time that elimination is subnormal. Apparently the chief function of sleep is to enable the body to clean house. Hence these patients need all the sleep they can get. Even twelve hours per diem, including an afternoon nap, is none too much in long-standing cases, if patients can get it. Few can attain this maximum, as the toxins in their bloodstream irritate the higher nerve centers and make them sensitive to objective impressions during sleep. Quiet sleeping places are not easy to come at now.

Emotion is the great proximate precipitant, and the migrainous appear all to be of unstable equilibrium. Even the

ordinary wear and tear of daily routine are trying to the typical patient, and to shield himself is all but impossible. For, after his family circle or business associates have witnessed scores or hundreds of seizures, they inevitably become callous, and his sufferings come to be regarded as partaking of the nature of hypochondria, or malingering. And this reaction acts as a spur to the patient himself, to his own undoing.

An outdoor, carefree life is the ideal, but few can arrange it. Excitement, especially sex, cards, social whirl, movies, overwork, tension, worry,—all have their price. A business or professional man may be compelled to retire, but a mother can scarcely abdicate, and for her, romping children, or a wayward adolescent, or a cocky servant, or cheating tradesmen may be as inimical as almost any factor imaginable.

Most people eat too much. Excess is normally burned up by the liver and thyroids. But the oxidizing capacity of the migrainous is already overtaxed. Hence, their intake should by experiment, be reduced to a minimum, which for those not engaged in manual labor, should probably not exceed 2,000 calories per diem. Animal proteids should be used sparingly, for when improperly converted into amino-acids by trypsin, they are decidedly toxic, and in the migrainous, pancreatic function is seldom perfect. And on this account, meat is best handled when comminuted, as in Hamburg steak.

The purin-producers, such as coffee, alcohol, tea, chocolate, should be abjured, for purins are hard to eliminate, and appear also to be specifically irri-

tating to the nerve centers The customary heavy meat meal at night should be abandoned, because it is then that the metabolism is at lowest ebb

A neutral blood plasma promotes elimination, and it is a biological commonplace that cell activity goes on best in a neutral medium Neutrality is promoted by the liberal ingestion, daily, of vegetable juices, most easily achieved by boiling the vegetables and drinking the pot-liquor Stewed fruits, if sub-acid, are also excellent Citric and malic acids are justly under suspicion Nearly all these patients suffer more or less from spastic constipation, and cellulose in large quantity tends to plug up the alimentary canal, hence the suggestion that needful vegetable juices be obtained by boiling, rather than by direct consumption of the fiber Cellulose, also, is broken down by bacterial action in the colon, a process productive of gas, irritating to both sympathetic and vagus, which are undoubtedly concerned actively in the migraine complex

Unless contra-indicated by vascular or cardiac or renal pathology, every patient should drink at least two quarts of liquid per day, it is expedient to complete this by 4 p m, as a full bladder interferes with sleep Many or most subjects do not tolerate casein, milk, therefore, is not for such Any excess of sugar is stored in the liver in the form of glycogen, and this storage and oxidation are incompatibles, hence the wisdom of using sugar very sparingly Fats are also not well borne Ben Jonson, in "Volpone", written in 1605, remarked the fact that the Dutch, much addicted to balls of butter, had to purge after such indulgence The

relative inability of the migrainous to handle fats well seems to be specific Gas-formers, such as the legumes, cabbage, oatmeal, spices and condiments, should be left severely alone Food purveyors are now pretty sophisticated Artificial preservatives, such as sulphur dioxide, and coal-tar flavoring extracts and colorings, are in extremely common use, and as a whole they are excessively deleterious to the migraine subject Unless or until all such are eliminated from his dietary, little or nothing can be accomplished for his relief To fend against them is almost impossible The preservatives are common in cured meats and fish as well as fresh, evaporated fruits, molasses and syrups, milk and cream, etc, and the coal-tar derivatives are in high favor with bakers and candy-makers

Empirically, a varied diet is best Apparently in all these patients, pancreatic enzymes are sometimes if not always lacking in quantity or quality, and trypsin can not break down starch, nor can lipase, proteids, nor diastase, fats Starchy foods must of necessity be the mainstay, and bread and butter with fruit or vegetable juices furnish very nearly a balanced ration Bread is the sole food that a civilized palate can endure at every meal, and it alone has been subjected to a temperature so high as 500° for so long a period as one hour, thus insuring the breaking down of the starch granules Personal idiosyncrasies in diet are mostly imaginary, though allergy is an undoubted fact Every patient should, by careful experiment, work out a menu for himself and adhere to it so far as possible But not every layman is competent to do this, and even dieticians are apt to

conclude, if shellfish or strawberries provoke in their own persons urticaria or the like, that such foods are unfit for human consumption. And migraine patients are especially given to ascribing, wrongfully, a given visitation to some viand previously ingested. Any food, taken in moderation, has in all likelihood, an extremely faint causal relation to any individual attack of migraine, albeit a pronounced allergic reaction might conceivably, like any other factor contributing to the lowering of the threshold of resistance, become the proximate precipitating cause of trouble. Generally speaking, gastronomic joys should be mostly tabu to severe types of migraine. In fact, the average subject would reduce his sufferings almost to the vanishing point, if only he could subsist without eating at all.

MEDICATION IN MIGRAINE

In the way of medication, the two sheet-anchors are cannabis indica (Herring's) and calomel. Cannabis is fool-proof, to all but the fools to whom bread-pills are habit-forming. It alleviates the pain during seizures, and by obtunding the sense perceptions slightly, it interposes a barrier or curtain between the patient and the slings and arrows of outrageous fortune, which imperviousness increases with use. And it does not check the secretions to any appreciable degree. Some patients are entirely relieved by cannabis as long as it is exhibited. Initial dosage should not exceed $1/12$ grain, repeated three or four times each day. The maximum objective is $1/4$ grain every four hours while awake. During stress, this maximum may be usefully

exceeded. Every migraine subject, unless abnormally susceptible to auto-suggestion, should be put through a course of this drug, it is the nearest approach to a specific.

To abort or break up any given seizure, nothing takes the place of calomel. Its handling is an art, which each patient must to some extent acquire for himself. For no two patients are precisely alike, nor are any two visitations identical in the same individual. Calomel is not altogether foolproof. It usually gives such relief, that there is a temptation to abuse it, it is hardly adapted to daily use, if for no other reason than that it must be excreted through the kidneys.

Upon the first prodromal symptom, which the patient can almost unerringly detect, he should take probably not less than $1\frac{1}{2}$ grains, though some patients may require more, to abort the impending attack. If this does not result, after 12 to 18 hours in relief, the initial dose should be repeated. If the pain persists, after another 12 hours or so, the sufferer should take his full maximum, which may be anything up to six grains or so. There is no sense in allowing the agony to continue for days. The total amount required bears very close relation to the degree to which the patient has flouted his limitations, previous to the onset.

Calomel in small doses is decidedly not indicated; for the disorder and concomitant metabolic explosion travel so rapidly that repeated tenth-grains can not overtake the procession of events. And after the complex has been permitted to attain its climax, it may be days before the pain can be stopped, and much longer before the

metabolic equilibrium can be restored Epsom salts, on an empty stomach, in plenty of water, should usually follow, after the pain has ended, albeit the salts may not be necessary, if the patient is taking a daily laxative For those patients who can not tolerate calomel, podophyllin, in 1/4 or 1/2 grain doses, taken in plenty of water, may answer as an imperfect makeshift

Every patient should induce, at least experimentally, not less than two loose evacuations daily Catharsis, by inaugurating profuse watery discharge from the rectum and sigmoid, undoubtedly carries off much toxic material and thus lightens the liver's load Aloin is the ideal laxative, and it alone may hold the lid on migraine for years, it can be exhibited for a lifetime with little or no ill effects discernible Anyhow, it is a condition, not a theory, that confronts these patients Addiction to laxatives may have drawbacks, but as a choice of evils, migraine is the greater Salines and enemata are not for prolonged use

After a siege, migraine patients

might well avoid violent exertion Pain weakens the heart-muscle, and if it is repeatedly overtaxed, the weakness may become permanent Imperfectly acting hearts are not uncommon in these subjects, and such may accentuate the complex Those who have chest-pains, extra systoles, arrhythmia, or chronic digestive disturbances might profit by a course of *digitalis*

The migraine subject of pronounced type is among the most miserable beings on earth, for the sum total of his sufferings, mental as well as physical, probably surpasses that which ordinarily falls to the lot of several hundred normal persons throughout their mundane existence Genius has been defined as the capacity for infinite pains-taking Without this faculty, to combat a lifelong migraine, is a task to tax the patience of a saint, and the courage of a paladin Mankind, however, as Osler justly remarked, has never emerged from the thaumaturgic age, and most migraine victims want to be cured by taking a pill

Presidential Address

American College of Physicians*

By S MARX WHITE, B S , M D , F A C P , *Minneapolis, Minnesota*

SELECTION by you as president for a year has allowed me to follow in the footsteps of men notable in medicine in this country. For the opportunity I am grateful. The honor brings with it great responsibilities.

This is the second meeting for which the president has been given the responsibility for the program of the General Sessions. This change was made two years ago in the belief that the president, using the prestige of his office, would have a more ready response from invited guests, domestic or foreign, and would have the opportunity to use speakers of his own choice rather than to select material voluntarily offered. The excellent program for the General Sessions presented by President Miller at Baltimore a year ago proved the wisdom of the change. This year, in spite of unusual difficulties, a program representative of the progressive spirit and of the latest advances in medicine is presented.

During the year which has elapsed since the Baltimore Session, the College has lost by death one Master,

twenty-five Fellows and six Associates. It is customary to publish in the *ANNALS OF INTERNAL MEDICINE* a biographic sketch of each, but some losses, because of their significance to the College, deserve special mention.

Dr Reynold Webb Wilcox of Princeton, New Jersey, died June 6, 1931, at the age of seventy-five years. He was a long time Professor of Medicine at the New York Post Graduate Medical School and Hospital, the author of many articles in American medical journals and of a well-known work on *Materia Medica and Therapeutics* which ran into ten editions. He was largely instrumental in the organization of the College, was a charter member and after the College had secured its charter on May 11, 1915, under the laws of the State of Delaware, he became the first president, continuing in that office until 1922, relinquishing it then to Dr James M Anders of Philadelphia, but maintaining an active personal interest in the College.

Dr George Martin Kober, born in Hesse Darmstadt, Germany, lived to the ripe age of eighty-one years and served his adopted country with distinction. In the last decade of the nineteenth century he directed attention to the pollution of the Potomac

*Delivered at the San Francisco Session of the American College of Physicians, April 6, 1932

River water as a factor in the spread of typhoid fever in the National Capitol, his home city, and was the first to point out also the part played by flies as carriers of the disease. His activities helped greatly to secure the legislation and appropriations by Congress necessary for proper sanitation in Washington. He remained active and interested in medical affairs until the very end of his career and the charm of his personality contributed much to the interest of medical meetings in which he was an attendant or participant in discussion.

The career of Dr Francis Xavier Dercum, world famous neurologist, closed suddenly and unexpectedly at the age of seventy-four years as he, then president of the American Philosophical Society, sat in the chair formerly occupied by Benjamin Franklin, and was about to open the 204th annual meeting. "He died", remarked a fellow scientist, "as a scientist would wish".

Dr Leonard M. Murray of Toronto was elected to the Board of Regents of the College in 1923 and served the two terms of three years each allowed by the by-laws. His contributions to our knowledge of cardiovascular disease are well known. He was only fifty-six when he passed away suddenly and unexpectedly in the midst of his career and left the memory of a charming personality and warm friendliness with those who were privileged to come in contact with him.

The death of Dr Aldred Scott Warthin, a Master of the College, at the age of sixty-four closed a remarkable and brilliant career while still in full tide. No single individual has

made so great a contribution to the welfare and development of the College and the ANNALS OF INTERNAL MEDICINE as he. Appointed editor in 1924 he brought the ANNALS to a most authoritative position in the medical literature of this country. The first four years spent by him in teaching at the University of Michigan, from 1891 to 1895, were in internal medicine under Dr George Dock. This colored his thought in later years, for no pathologist of his time thought with and for clinical medicine more assiduously or effectively than he. This attitude rendered him particularly useful and acceptable as editor of the ANNALS. He understood and labored for the interests of clinical medicine. During the last year of his life he occupied himself particularly in the aims of the College. He felt that the College was just entering its greatest period of usefulness. Shortly after the Baltimore Session, and a few hours before his death, which came unexpectedly, he dictated a long letter to me, charged as I was with the responsibility for the program of this present session. In this letter he said, in part "I think that I would like to be on the program next year at the California meeting. So many men have written to me concerning various matters pertaining to the College that I would like to make an address bearing upon the future of the College and its functions. The editorial which I had in the number preceding the meeting of the College apparently excited a good deal of thought and I am glad to see that there is a growing appreciation that the College should sometime have something more than mere scientific work.

I think that there is a real opportunity to make the College a more vital force and influence in American Medicine than it is at the present time" The letter is unsigned but was forwarded to me immediately after his demise and breathed the spirit of the man. What the concrete suggestions were we know only in part. He had never formulated them completely to anyone, so far as is known. Their spirit, however, was one of a positive attack on the problems—cultural, professional and economic—facing at least that portion of the medical profession represented by the College. They were the outgrowth of a rich experience and a trained and cultured mind. No quotation from this editorial, detaching a part from the whole, would adequately represent his thought. Rather would I refer you to its entirety in the *ANNALS* for February, 1931.

It is a source of personal gratification to be able to pay tribute to the man who has carried these many months the work so abruptly relinquished by Dr. Warthin. At a sacrifice of time needed for other interests, Dr. Carl V. Weller, Professor of Pathology at the University of Michigan, has edited the *ANNALS OF INTERNAL MEDICINE* in a manner beyond criticism. The editorial writing has been carried on with eminent satisfaction to all, welcome changes and improvements have been made and the rapid growth in size, character and influence, well under way during Dr. Warthin's lifetime, has continued without interruption. To him we express our profound gratitude for this loyal and effective service.

The growth of the College contin-

ues without interruption. The mechanism by which a period as an associate is a prerequisite for fellowship, became operative with the close of the year 1931. Time alone will demonstrate whether this change will accomplish its purpose. While the College has not as yet become unwieldy because of size, it was apparent that such a time was approaching and that it was desirable to prevent, in a healthy and logical manner, too rapid expansion. The period of time required as an associate will give the College an opportunity to appraise the spirit and accomplishments of each candidate for fellowship, and will give the candidate an opportunity to learn more fully the purposes and service fundamental to the success of the College. The new plan makes it mandatory that each candidate for associateship be scanned with as great care as that formerly used in selecting nominees for fellowship.

I call the attention of the Fellows of the College again to the opportunity presented in life membership. While economic conditions during the past two years and more have slowed accession in this department, those in position to do so have an opportunity even greater than before. Moneys derived from life memberships are set aside in a separate endowment fund, through which the scientific aims of the College will be advanced. The College will attain that influence and power at which we aim only when its resources are adequate to accomplish its purposes. The endowment fund may receive accessions in many ways. Life membership should be purchased not by the few, but by the many. Let us be reminded that the initiation fee is a credit already

paid toward the cost of life membership. The number, instead of about thirty, should be three hundred and more. Donations, small when necessary but generous if possible, should be a habit and not a rarity. Arrangements for bequests at the death of members or of others interested in medicine should be discussed and encouraged by us. To those of us unable to purchase life membership, I would suggest a bequest of an equal sum *In Memoriam*. Philanthropically minded friends and clients should be told of the opportunity for continued usefulness of their moneys under skillful direction by the Board of Regents which is a continuing body of men wise in the use of funds for the advancement of medicine. Such funds as donations or bequests to the College are free from gift or inheritance taxes, an inducement to many at a time when taxes of all kinds are becoming a burden. Such matters as these should become subjects of free conversation with us, for the philanthropist often keeps his purposes in hiding and his gifts may be revealed only by his testament. We have made a beginning, \$52,400 since 1926. This should give us courage, but it is too slow. We would each like to see the fund in effective operation during our lifetime. With enthusiasm and interest on the part of our entire membership, or of only a significant portion of it, I am confident that many sources not yet uncovered could be found for the endowment fund. Additions of any kind, many and small, fewer and large, would swell it to a place of real power and usefulness.

As a new departure, an example of activity outside of the primarily ex-

pressed purposes of the College, we have had this evening the presentation of the John Phillips Memorial Prize given annually by the College in memory of that beloved physician, who gave his life in so tragic a manner that others might be saved. A member of the Board of Regents from 1923 until the time of his death in 1929, he served the cause of Medicine and the College with distinction. It is fitting that his life and work should be brought again to mind through the presentation of the prize and by an address by Dr. Oswald T. Avery, the distinguished first recipient thereof.

Our progress depends upon the devotion, the intelligence and the continued application of the coterie of men devoting their lives to the advancement of knowledge. The direct financial rewards for research in medicine and in other branches of science are pitifully meager and the workers are often seriously handicapped by lack of the support needed in their pursuits. To this group of men every honor is due and by them every financial aid is used to further their research. The very fact of devotion to their calling is an evidence of their earnestness of purpose. Every aid rendered them brings its return many fold. The College is in the forefront in its encouragement of scientific work. Money is needed in order to further this and similar enterprises. The endowment fund, aided by life memberships, will exercise a most potent influence in this direction.

The past year has seen cancellation of many medical meetings and Congresses planned in Europe. There the change in economic status has reached into every phase of life and this

restricted activity has thus affected the time given to consideration of the most fundamental human needs, of health and physical welfare. To the west of us Japan and China, profiting nothing by the horrid experiences of newer civilizations, have been employing the age-old methods of Martian struggle, and medicine there is compelled to occupy itself with binding up wounds, removing the sick and injured from the lines of communication and, in so far as possible, restoring them to their destructive occupations. In the meantime, progress in constructive medical thought and effort is halted. In this continent we are blessed with a common language and understanding. The long boundary between Canada and the United States needs no military fortification or patrol. We have a common inheritance and understanding and for long have been able to adjust any differences of opinion by peaceful means. We can thus continue our constructive efforts. With our neighbors on the south, although handicapped by differences in language, we are at peace and will so remain. Our common interests have taught us to avoid destructive means of settling questions between nations. Our situation, therefore, calls for increased effort in the arts of peace.

When discussing the functions of the College we should be reminded of our duties and privileges in the American Medical Association, since all forms of activity of those licensed to practice medicine are there represented. To it we individually and collectively give our allegiance and support. Its great medical *Journal* and *Hygeia* lead in their respective fields of general

medicine and surgery and of popular hygiene. Two of the major activities of this association are of such significance to medicine that they deserve particular mention, not only for themselves but as examples of what collective efforts in a great association may accomplish. The first of these is that of the Council on Pharmacy and Chemistry. This Council has done, and is doing, a service of incalculable value to the medical profession in freeing us from the need of reliance on secret and proprietary preparations and has given us standards by which all remedies may be judged. Not only as individuals but as an organization there should be specific and expressed approval of the work of this Council and an active adherence to the principles it has laid down. Only by strict compliance with its requirements can we hope to keep therapeutics on the high plane it should occupy, free from all secret remedies and with positive knowledge, openly arrived at, of the character of all therapeutic procedures.

The second major activity in the American Medical Association to which our support is due is that of the Council on Medical Education and Hospitals. The association, together with the forces and organizations whose support it has enlisted, has been a major factor in placing medical education on the high plane it now occupies in most states. The elimination, now almost complete, of the low standard commercial medical schools and the establishment of standards more nearly uniform throughout the country has been a service of prime importance. In the matter of hospitals the activities of the Association has been limited largely

to the educational aspect, the training of internes, and the opportunities for special training for residents. The important function of standardization of hospitals was assumed by the American College of Surgeons while the Association slept, and before our own organization, to represent medicine as that college represents surgery, was developed. All credit is due that college for its enterprise and for the energy with which its standardization project is carried out, but the anomaly of surgeons posing the standards for the physician is apparent to anyone who has the welfare of the whole profession, and of the patient as well, in mind. It is probable that only the assumption of greater responsibility by the American Medical Association will help to correct this unbalanced state of affairs. Renewed attempt to further the interests of medical service in standardized hospitals may yet avail. In spite of this disadvantaged position of internal medicine at the present time, the public is acquiring a growing appreciation of the part to be played by hospitals in diagnostic and medical forms of service. While it is, undoubtedly, true that in many hospitals surgical service is the chief aim, it is equally true that the growing complexity of equipment necessary for adequate medical service is forcing the patient with non-surgical disorders into the hospital where the proper equipment can be provided and more effective study made.

Is it possible that there is a distinction between the medical and surgical interests of a patient? I cannot agree that there is. The interest of the patient demands, except in emergencies and with the diagnosis readily made, a

thorough survey to discover first of all the character and the sum of conditions and disorders present and, secondly, not primarily, the therapeutic procedures to be applied. The degree of skill and experience necessary for the solution of a diagnostic problem is just as great as for the performance of an operation. There has been a tendency to foster the idea that long training and special experience are necessary to make a surgeon, but that anybody can make a diagnosis, or can carry out medical lines of therapy with tolerable accuracy. In fact, during the last two years, particularly, it has been a source of some amusement, if not pain, to see some of our erstwhile surgical confreres indulging in the mysteries of digitalis, the diuretics and some of the rest of our wellworn armamentarium in the intervals between their now all too infrequent operations. At some time in the near future it may be necessary for some organization, either this or the American Medical Association, to insist upon an adequate recognition of medical, as well as of surgical, values in hospital service. It is to be hoped that the invitation to that end may be given by the organization which has so far kept that function to itself. By this means a service of greater value, both to the medical and surgical interests of the patient, could be performed.

The primary purposes of the College are well set forth in our constitution. There has been much discussion as to additional activities a body such as this might well undertake. To the present it has been thought advisable to concentrate on making the foundation sound and sure, and on assuring a

membership representative and inclusive of the men in the United States and Canada best fitted by character and training to understand the problems of our special fields. Standards of character and attainment have been set but there has been no thought of limitation in numbers. As a result of this policy the College has attained in the sixteen years of its existence a position of influence in internal medicine. The annual session has been the outstanding and most valuable meeting of the year. The clinics and demonstrations at the place of meeting by the men of the schools and hospitals have given those attending the session an insight into the character and breadth of the medical work in each of the great cities visited, thus giving an opportunity to each Fellow to compare the work in his own locality with that in widely scattered medical centers throughout the country. This in itself is one of the most valuable features of our sessions.

At this point I should like to call your attention to the extraordinary depth and breadth of the clinical program arranged here in San Francisco, and to thank, for the College, Dr Wm J Kerr, who has filled with distinction the position of General Chairman.

With the cultural background of the Fellows of the College it is natural that the history of medicine should receive considerable attention and should have at least some place in our program. In this, and the two sessions preceding, we have given it more attention than in previous years and have sensed a favorable response on the part of the membership. This year we find this stimulating and wholly enjoyable ac-

tivity of many of our Fellows exemplified not only in the general sessions, but also in the series of exhibits and papers on medical history in the clinical sessions. Historical considerations, however, can claim only a minor portion of our time and other organizations among medical men are giving it more serious attention. To them we extend every aid and encouragement.

We glory in our past, not only remote, but so immediate that it may be called the present. The achievements of medical science need no catalogue here. The conquests of infectious and other forms of preventable disease, the consequent prolongation of life, the prompt application of all forms of scientific discovery to our problems as we have cast off the cloak of mystery once worn, have all placed medicine in the forefront of this progressive age. Our scientific problems loom large, but are being attacked by the best minds on every hand. The serious difficulties confronting us as a profession today lie as much in the social as in the scientific field.

Broad and vexing questions in what may be called the field of medical economics are constantly arising. Their solution needs wise and unselfish leadership. The medical profession is taking what is believed to be its proper part in the five year study of the Committee on the Costs of Medical Care. Some results of these studies have appeared from time to time and the five years allotted will have elapsed at a relatively early date. Some definite recommendations will be made. It is hoped that some new applications of our age-old principles will be suggested and that some new, or so far relatively

untried, methods of organization will receive attention and may be recommended, at least for trial. That the committee can solve, even within a five year period, all of even the major questions posed is not within the bounds of human possibility.

The existence of the committee has made the public more acutely aware of our economic shortcomings than of our virtues, and whether we wish it or no, forces not of our own choosing will attempt to invade what we believe to be properly our domain. The paramount interest is that of the public. Public interests are often expressed in the form of legislation, but legislative bodies are notoriously lacking in an appreciation of medical values and it is only when guided, or driven, by an aroused medical opinion that legislation actually in the public interest has been secured. One doubts legislative wisdom in the medical field, or for that matter in any other field where science is involved. One needs only to cite the legislation involving cults in most of our states for illustration.

Dr Ray Lyman Wilbur, writing as Chairman of the Committee on the Costs of Medical Care, states pointedly that the achievements of medical science must be made available to all, that the only way this can be done is through organization, that the organization of medical facilities will be painful to some even if necessary, and that we must make many shifts and changes in our thinking if adequate medical services are to be made available at reasonable cost to the citizens of this country. Two questions arise. What shall be the forms of those organizations? Shall they be determined by states or

communities, or shall they be by medical men themselves?

The various ways in which organization may affect medical service as it relates to disease and disability, i. e., to the practice of medicine, may be thought of as in four great groups.

1. The state and other political units which already provide for certain medical needs of the public. Among these is custodial care of the insane and the incompetent. There is provision for isolation of those whose infectious disease would otherwise be spread throughout the community. There is the study and control of public health relations, and there is, finally, medical service in all its forms for the indigent. In all these ways the state, through organization, can provide service better than the individual. Many people affected by these services could pay for them if necessary, but with the public needs paramount it is clear that the state can perform the service with the welfare of the state in mind. It is only when the state proposes to serve in other ways the individual who is able and desires to pay for individual medical service that we take notice. In the medical mind, the extension of state medicine beyond the needs of police power, public health and public service is inadvisable, largely because of the knowledge that it will do away with the valuable personal relation between physician and patient, necessary if the interests of the patient are to remain primary.

2. Lay organizations, lodges, benefit associations and the like have grown in this country, and in many instances continue to grow in spite of the opposition of the medical profession in the

locality In a few instances only have they succeeded in maintaining the high level of professional attainment we seek to guard In these organizations the continued employment of medical men is subject to many considerations other than their ability to deliver an adequate service Insurance companies, either in relation to such activities as life, health and accident insurance, or as a new project of hospital or sickness insurance, or a combination of both, are becoming interested Probably because there is no firm actuarial basis for premiums, and because the past experience in disability benefit is unfavorable, the old line life insurance companies seem to be reluctant to enter this field The work of the accident insurance companies is principally in the protection of their policy holders and we may expect no constructive efforts from that source In all these fields the primary control is lay, rather than medical The medical man is the employee and not the principal In all these organizations, the cost is met by prepayment of a fixed charge, which, though it may be varied somewhat from time to time as the result of experience, is nevertheless relatively stabilized

3 Hospitals are more and more providing centers about which medical men may group themselves The inter-relations of the members of the staff are often only those of proximity, but more and more close ties of interest are being formed with the hospital as a center It seems quite probable that valuable development along these lines can be fostered and that common interests, with more or less definite co-ordination, can be built in and around

these institutions In teaching hospitals a staff of salaried whole-time men, teaching and practicing the various specialties and covering the entire field, is practicing group medicine When in a state owned public hospital with such a staff the number of individuals treated is not limited by the needs of material for teaching, then the institution is furnishing a form of state medicine An interesting form of group medicine often closely related to teaching hospitals is seen in the Student Health services in many of our large colleges and universities

4 Physicians are organizing in many and various ways to manage their own affairs as they relate to the practice of their profession In some instances such organization involves only a combination of facilities in hospitals, or in more or less loose aggregation, for the purpose of securing laboratory and technical service The formation of more closely knit groups in private clinics has been a development in recent years In such groups, either related to or separate from hospitals, the personal relation between physician and patient will be maintained These groups are formed primarily for the purpose of providing every needed facility for fact finding and for closer integration of the work of one specialty with another In a properly constituted group each man may be said to have a dual function The first is as a specialist in his chosen field, the second is as a general practitioner guiding and conserving the interests of his particular patients Specialism in a group becomes less hard and fast than when a man is practicing alone and the specialist in a well constituted group be-

comes more of a general practitioner than he ever would practicing his specialty alone. Group medicine will be in favor with the physician only when he realizes that he can be a part of it, and that his facilities can be thus enormously increased in a manner using each to its capacity. Without some such mechanism the physician cannot own and control his laboratories and his apparatus without an undue and often depressing financial burden. The group in its ideal form represents an expansion of the partnership principle, and allows a community of interest among medical men obtained in no other way.

In a recent discussion of some economic considerations influencing the future of the practice of medicine, at the Annual Congress on Medical Education, Medical Licensure and Hospitals held in Chicago in February, Hugh Cabot, in addition to considering the various groupings possible in medicine much as in the forms outlined above, made the suggestion that "big business" could make a valuable contribution to the forms of medical service. We will grant at once that the dollars made in big business can be put to work for human welfare in forms of medical service. This has been abundantly demonstrated through the many bequests already made, and through the great foundations now in operation. That the methods of accumulating those dollars could well be used in medicine seems impossible. The ideals and practices of big business and of medicine are in many ways diametrically opposed. If by big business there is any implication that a corporation could practice medicine as a corporation, it is to be hoped that question

is already settled in the negative. Business advertises itself by headlines with an eye to selling the product. Medicine *desires* to advertise itself only by the character of its service and results. When medicine advertises for sale that which the great bulk of the public wants, which is a cure and a cure only, it is open to a conviction of misrepresentation. The cure cannot be guaranteed. In the mind of the public, as well as in the mind of the medical profession, big business does not represent the ideals for which medicine should stand. The dominating influence should be that of service and not that of the financial return.

Speaking broadly, the economic principles underlying the provision of medical service will be determined either by the medical profession or by politicians. In the past we have been most influential in determining our qualifications and in setting high standards for ourselves, but having accomplished this, pressure from without—political pressure if you will—has left us woefully surrounded with a fringe of inadequately prepared cultists, whose chief claim to following lies in hasty and correspondingly faulty methods of approach to the problems of the sick and disabled. The cults and quacks rely upon salesmanship rather than service to secure their following. We have been content to rely upon service and are probably, as a whole, the worst salesmen in the world. I would not put salesmanship above service. To do so would be to lower ourselves to the level we decry. It is true, however, that too large a portion of the public fails entirely to understand our attitude and is too little aware of the solid foundation

on which the science of medicine rests. We are forced to recognize the fact that we have not adequately presented our point of view, or the real significance of our service to the public as a whole. This presentation cannot be made and controlled by individuals, for when so done personal interests creep in and the interests of the profession, as of the public, are likely to become secondary. The task of an adequate presentation can be performed only by and through the organized bodies representing medical opinion freed from individual concerns.

In England and Germany the imposition by legal enactment of certain intolerable and debasing conditions has been due in largest part to the refusal or failure on the part of the medical profession in these countries, to meet in adequate form the fundamental medical needs of the peoples involved, or at least to show clearly where these needs are met. Whether or no legislative enactment of similar character lies before us we do not know. Since with us medical legislation lodges, for the most part, with each of the forty-eight states in the Union it is not probable that there will be any attempt at countrywide legislation of a similar character. We are confronted today, however, with the prospect of an enormous expansion of state medicine and hospitalization by those seeking government relief of non-service disability in Veterans' Hospitals and Bureaus. This project is being fostered politically in spite of the fact that the number of hospital beds now available in the country is adequate for the needs and that there are at hand methods of securing adequate medical service for the

veterans, other than by the provision of new hospital beds. These methods would meet the needs, would provide better service without removing the individual from his immediate locality—an expensive and disruptive procedure—and at the same time would avoid an enormous addition to the already over-weighted tax burden.

It may be that we are fortunate in this country in the fact that medical legislation lodges with the States and this fact may minimize the tendency to crank legislation since the questions involved are brought more nearly home to the people concerned. Further, an experiment in medical economics shown to be impractical in one state can be avoided by others.

In studying the needs of our profession, it is well to bear in mind that we exist primarily not for our own welfare, but to provide a certain service to the public. The public interests are paramount and come before our own. In the statement of principles of medical ethics they are declared to be primarily for the good of the public and we should bear in mind in every consideration that only in the degree that we serve the public needs can we hope for, or receive, public approval. In planning our relations to the public, however, there is a question to which I should like to invite your attention. It is this: Who is best fitted to understand the needs of the public when considering the forms of medical service? Is it the physician as representative of the medical profession, or is it the politician as a representative of the public, where, after all, final action will be lodged. Occupied as we are with better things, we are too prone to

believe that our point of view from its own weight and rectitude will prevail. The man, or the profession, that relies alone on these essential features to advance his cause, is doomed to disappointment. *For success in the economics of medicine, as well as in the science and art, the master word is work.*

It seems clear that if we, as a profession, can command effective leadership and exhibit wisdom and capacity, we can continue to provide in adequate form and with proper costs the needed service. This will require constructive statesmanship and unending effort. By these means the danger of political control, of debasing conditions and of state medicine can be greatly minimized, and if they are avoided, it will be by these means alone.

The American College of Physicians will continue to stress the importance of adequate training as preparation for service in medicine. It will continue to put character in the forefront of requirements of the physician. Medical science will be served and every effort will be made to encourage those who, without thought of self, labor unceasingly in the laboratories and in the wards that the boundaries of knowledge may be extended.

The study of the history of medicine will be encouraged and the cultural value of a knowledge of our past will receive recognition. Knowledge, and the power that knowledge gives, will be fostered at every opportunity. These aims have become a part of the things for which the College is known to stand.

Is it time that the College should move out from this more delightful

realm into a consideration of fields not only cultural but economic? If we were living only so long ago as the date of our charter we could, with perfect equanimity and justification, limit our deliberations to the quieter and more enjoyable features of our profession. It would be a joy to step into the study, the laboratory or the ward and to let our considerations be confined within those walls. If we could be sure that the walls would continue to shelter us this might be a safe procedure. It would certainly be the most delightful life to most of us.

Sixteen years, however, have led us into an era of changes in the economic structure more rapid than we yet realize. Like all life, medicine is not static but is dynamic. Its dynamic power, however, is only what we, collectively and individually, make it. With an active and virile membership reaching into every corner of the land it is necessary that we give consideration, not only to our science, our culture and our comfort, but that we take an active part in the changes in the economic structures on which we stand. Our part can best be the encouragement of the method of science, the processes of trial and error in fitting the service of medicine to the needs of the community. Medical knowledge has been won by long and arduous application. The road by which we can arrive at an equal understanding of the economic values in medicine is equally long. There can be no loitering if we are to continue to lead. There is much to learn along the way and it is only by entering the path that we can expect to follow it.

Editorials

THE SAN FRANCISCO SESSION OF THE AMERICAN COLLEGE OF PHYSICIANS

As the special train of the American College of Physicians made its way westward, gathering small increments at various junction points but with its total passenger list not exceeding seventy-five persons, the statement was frequently heard that it was exceedingly unfortunate that for this year of all years a far-western city had been chosen as the place of meeting of the College. Pessimistic prophecies were voiced as to a probable failure of attendance for it seemed very evident that Fellows from the Middle West as well as from the East were finding it impossible to make the journey. The postponement of various European congresses was mentioned frequently as indicating the difficulties facing such organized endeavors. Yet when San Francisco was reached and there was opportunity to circulate among the gathering throng it was evident that pessimism was ill-founded. This became a certainty when at session after session of the general meetings the Ballroom of the Palace Hotel was found to be filled to capacity. Official figures of the registration at the Sixteenth Annual (San Francisco) Clinical Session are now available. The total attendance was 1,585, consisting of 132 visiting ladies, 107 exhibitors and 1,346 members and guests. It is

true that the attendance was largely contributed to by those resident in the Pacific States, who furthered the success of the undertaking by their commendable zeal and loyalty. Yet the wide geographical distribution of those registering was a source of surprise and of gratification. The only states not represented in the attendance were Alabama, Arkansas, Georgia, New Hampshire, Rhode Island, South Carolina, Virginia, and Wyoming. China, Hawaii, and Panama were each represented by a single registrant. In order of numbers attending from each state, California was first, Oregon, second; Washington, third; Minnesota, fourth, Pennsylvania, fifth, and New York, sixth.

The General Sessions have established an impression, which has been voiced by many, that taken collectively they constitute the outstanding annual event in Internal Medicine in this country. The San Francisco Meeting went far to confirm this feeling. The wealth of material, the general excellence of presentation, and the skillful grouping of related subjects all showed the wisdom with which the program was organized. The sustained attendance throughout meetings which were rather too long, and too hurried, showed that the General Sessions were appreciated.

The richness of the clinical material which San Francisco and the neighboring communities set before their visitors must be mentioned also. Mem-

bers and guests were in a more or less constant state of mental unrest in endeavoring to choose among the many programs offered. On the clinical programs there were about 500 presentations. Herein has developed a source of embarrassment for the Editor of the ANNALS as well. In its present convenient size, with the scientific material limited to approximately 1,500 pages for a year, the ANNALS can publish about 140 papers in each annual volume. The General Sessions provide about 65 papers, which are considered primarily to belong to the College and already earmarked for the ANNALS, if suitable. Due consideration must be given to the continual influx of manuscripts throughout the year from which choice must be made, for the pages of the ANNALS must not be restricted to material presented at the Annual Session. If, from this group of material, an amount is chosen equal to that derived from the General Sessions, it is evident at once that but few papers from the clinical programs can be published. This is greatly to be regretted for many of the clinical presentations have been quite as significant and as admirably done as those upon the general program. So great is the total volume of material available that any increase in the size of the ANNALS, within reasonable limits, could not appreciably relieve the situation.

CIVIC PRIDE AND PUBLIC HEALTH

Municipalities may properly boast of their natural advantages, their parks, public buildings, and commercial and industrial development, but one of the best measures of the intelligence, so-

cial-mindedness and governmental efficiency of a community is its public health record. Too often claims in this field are presented only as generalities, expressed by such terms as 'healthy,' 'healthful,' or 'salubrious.' The Journal of the American Medical Association has rendered an important service in this respect by the publication of an annual comparative survey of the typhoid fever death rates in the large cities of the United States. The twentieth report* in this series has recently appeared. It is particularly the group of food- and water-borne diseases which would appear to provide the best index of the success of the public health endeavor of a community. In the report of the survey to which reference has been made, twelve cities of more than 100,000 population are placed on the honor roll as having had no deaths from typhoid fever during the year 1931. These are Cambridge, Des Moines, Fall River, Flint, Long Beach, Lynn, Reading, Somerville, South Bend, Utica, Waterbury, and Wichita. Fifty additional cities had rates ranging from 0.1 to 1.9 deaths per hundred thousand, and five of these reported that all of their typhoid deaths were of nonresidents. The non-resident deaths create a problem for it is obviously as unfair to exclude certain of them as it is to include all. A uniform and fair method of distributing them is not available. Another element of unfairness is introduced by the necessary inclusion of the post-vacation cases. This problem is world wide. It is the chief source of typhoid

*Typhoid in the large cities of the United States in 1931, Jr. Am. Med. Assoc., 1932, XCII, 1550-1552.

morbidity and mortality in many large cities—Vienna, for instance. Perhaps the inclusion of deaths from typhoid fever in the resident population when the infection has been acquired away from home, is justifiable on the ground that the community shares the responsibility of securing protective vaccination for its citizens who seek a more primitive mode of life for their vacation period. So low is the total number of deaths from typhoid fever in most communities, a single sharply localized outbreak may play havoc with an otherwise good record. Twenty out of the thirty-one deaths in Cleveland in 1931 occurred in an outbreak at the State Hospital for the Insane. This institutional epidemic gave Cleveland a rate of 3.4, while without it the rate would have been 1.2. A low rate, i.e., less than 1.0 per hundred thousand, in a large city may indicate a greater achievement than a 0.0 rate in

a community of much smaller size. The most gratifying results are those which show a consistent improvement over a period of years in the course of which a relatively high rate has been brought down to the minimal figures of the first rank. Milwaukee, for instance, has changed a rate of 27.0 for the period 1906-1910 to 0.3 for 1931. Chicago had a rate of 15.8 in 1906-1910, and of 0.4 in 1931. Cincinnati has advanced from a rate of 30.1 in 1906-1910 to 0.4 in 1931. Many such examples exist. Comparative studies of the type presented in this survey lead to a very proper spirit of emulation among municipalities. This stimulating analysis can be applied not only to morbidity and mortality from infectious diseases but also to such public health problems as arise from automobile accidents, injuries associated with crimes of violence, and suicide.

Abstracts

Cancer and Tuberculosis, with some Comments on Cancer and Other Diseases. By EDWIN B. WILSON and HELEN C. MAHER (Am. Jr. of Cancer, 1932, xvi, 227-250.)

From pathological and epidemiological evidence opinions at variance with one another have been arrived at in respect to the simultaneity of cancer and tuberculosis. Some have maintained that cancer and tuberculosis are antagonistic, some that one disease favors the occurrence of the other, and some that the incidence and progress of the two conditions are independent. (This question has been considered previously in the ANNALS 1929, III, 495-500, and 1929, III, 501.) The difficulties involved in arriving at a sound judgment and the various statistical fallacies which must be avoided or mini-

mized are considered in the course of a mathematical treatment of the problem. It was concluded that there seems to be little or no evidence in favor of an antagonism or dissociation between cancer and tuberculosis and a considerable variety of evidence in favor of a slight degree of positive association between the two. Until better estimates of morbidity rates are available one should not be dogmatic over the matter and may well admit that for practical purposes cancer and tuberculosis may be regarded as independent. There seems to be considerable evidence that cancer of the esophagus is associated with pulmonary tuberculosis, as might perhaps be natural if the condition resulted in a long-continued malnutrition. At present there seems to be

no material which should lead to a judgment as to whether cancer and tuberculosis tend to originate in the same persons because of constitutional diathesis, or whether the association might result merely from an invasion of one of the processes by the other or a lowered resistance to the progress of one of the diseases owing to a debilitation by the other

Lead Poisoning in Children By H S MITCHELL, M D (Canad Med Assoc Jr, 1932, xxi, 546-549)

Lead poisoning in children exhibits certain peculiarities which require emphasis. Unlike the usual occupational hazards of adults, the exposure is more subtle. The juvenile system reacts more severely to a much smaller exposure, and the manifestations of intoxication are different. Except in rare instances of food-poisoning, lead is usually acquired as a manifestation of pica. Lead painted chairs, toys, and cribs [also porch railings, Editor] usually furnish the source. Such objects may be found to be devoid of paint in the areas which can be reached by the mouth. Children with lead poisoning are usually more or less irritable, but they seldom complain of colic. Constipation is almost invariably present, but seldom remarked upon by the parents unless they are questioned about it. There is usually some pallor. A lead line may be present, but less constantly than in adults. Peripheral neuritis frequently develops, and the legs are more often attacked than the upper extremities, in contrast to adult cases. Most important of all are the frequent cerebral manifestations which may be abrupt in onset. Two cases are presented illustrative of lead poisoning in children. One was referred as a case of poliomyelitis because of wrist- and foot-drop, and the other for generalized convulsions of sudden onset. The second case showed a heavy epiphyseal line upon x-ray examination. Treatment is discussed with due regard to the principles of preliminary concentration and fixation of the lead in the bones (especially important in presence of neurological crises) and subsequent slow elimination.

Coronary Disease in 100 Autopsied Diabetics By M H NATHANSON, M D

(Am Jr Med Sci, 1932, clxxxiii, 495-503)

Since the discovery of insulin, the clinical picture of diabetes has been changing. Whereas before, malnutrition, infection, acidosis, and coma were the chief dangers, vascular disease is now playing a greater part. Joslin has reported that since the introduction of insulin the deaths from vascular disease in diabetics have increased from 28 to 47 per cent. In the present study the records of 100 diabetics were analyzed with special reference to the cardiovascular pathology. The coronary arteries were considered as diseased only when there was marked sclerosis with definite narrowing and partial obliteration of the lumen of one or more large branches. The results were controlled by comparison with the incidence of coronary sclerosis in general autopsy material. The entire series of 100 autopsies upon diabetics showed an incidence of severe coronary disease of 41 per cent. Above the age of 50 years the incidence is 52.7 per cent as compared with 8 per cent in a series of non-diabetics of the same age. The frequency of coronary disease was found to be almost as high among the female diabetics as among the male. In diabetics with gangrene, the incidence of coronary disease was higher than in the uncomplicated cases. The essential cardiac lesion in diabetes is coronary sclerosis. Other types of cardiac disease are of relatively rare occurrence.

Renal Function in Exophthalmic Goiter and Myxedema By J LERMAN, M D, and A J BROGAN, M D (Endocrinology, 1932, xvi, 251-256)

Because of a number of circulatory antitheses between exophthalmic goiter and myxedema it seems probable on purely *a priori* grounds that the effect would be to increase renal function in exophthalmic goiter and to decrease it in myxedema. A total of 75 patients with exophthalmic goiter and 22 with myxedema were tested by means of the phenolsulphonephthalein test as described by Rowntree and Geraghty. It was found that the renal function of myxedema patients, as determined by this method, is slightly but consistently lower than that of exophthalmic goiter patients in all age groups except in

the group 60 years of age and over. The function in both diseases is probably within normal limits. In exophthalmic goiter renal function varies with age. Up to the age of 50 the function is more or less constant, but after 50 it diminishes rapidly. In the smaller group of myxedema patients studied, such a correlation with age did not appear. No relationship was found between the degree of phthalein excretion in exophthalmic goiter and myxedema on the one hand and the basal metabolic rate or the degree of anemia on the other. A slight relationship between phthalein excretion and pulse pressure was found in myxedema only. Thus the data presented offered no support to the concept that permeability of renal tissue is significantly altered in hyperthyroidism or myxedema.

The Dynamic Bronchial Tree By CHARLES C MACKLIN, M.D. (Am Rev Tuberculosis, 1932, xxv, 393-417)

An attempt is made to visualize the *locus* of pulmonary tuberculosis. The purely conducting part of the bronchial tree (that is everything up to, and including, the fine, smooth-walled bronchioles) is envisaged as undergoing a lengthening with inspiration and a shortening with expiration, and the details of this process are explained with diagrams. The peculiar shape and mode of action of the pleural cavity make it necessary to shift the lower part of the lung during inspiration in a downward, forward and outward direction, if the part above and behind the hilum is to expand properly. The root of the lung is of very great importance in this movement, of which the reverse phase is seen in expiration. It is suggested that the normal flexibility of the root may be impaired from disease processes, and that this will hamper lung ventilation, especially in that part lying above and behind the hilum. The advisability of ascertaining the normal range of movement in the root, particularly in children, is stressed, and the possible relation of interference with this movement to pulmonary tuberculosis advanced (Author's abstract)

A Thyroid Hormone in the Blood and Urine in Graves' Disease By LEO R HIMMEL-

BERGER, Ph.D. (Endocrinology, 1932, xvi, 264-266)

In addition to applying the biological test described by Dresel to the blood of 24 patients diagnosed clinically as exophthalmic goiter, the urine of 17 of the same group was similarly investigated. In but 13 of these did the mice live to complete the test. The hormone test on the urine was positive in 10, indefinite in 1, and negative in 2. These two patients lacked the lymphoid tissue in the thyroid which is considered indicative of Graves' constitution. It was concluded that when the blood serum or urine from patients with Graves' disease is injected into mice, a substance capable of disturbing liver function can be demonstrated. In the limited number of cases studied, the presence of the hormone was found to parallel the presence of lymphoid tissue in the resected thyroid glands, thus lending further support to the view that lymphoid areas are an essential part of the pathological picture in Graves' disease. It is suggested that the demonstration of this hormone in the urine or blood serum might be useful as an aid in differential diagnosis and that the method should prove to be of value in the experimental study of Graves' disease.

The Distribution of Blood Cholesterol in Cancer By HELEN R DOWNES, Ph.D., and GEORGE T PACK, M.D. (Am Jr of Cancer, 1932, xvi, 290-296)

Various studies of the cholesterol content of the blood in cancer have been undertaken from time to time. One of the most promising results was the observation of Mattick and Buchwald, in 1928, that in 85% of the 100 cases of cancer studied by them, the cholesterol content of the plasma was found to be higher than that of the whole blood, while 80% of the healthy persons studied showed this relationship reversed. In the present investigation it was found that there was no constant relationship between the concentration of cholesterol in the whole blood and in the plasma in a series of 63 cases of malignant tumors and allied blood diseases. The cholesterol content of the blood was not increased above normal in the presence of cancer.

Reviews

The Practitioners Library of Medicine and Surgery Supervising Editor, GEORGE BLUMER, M A (Yale), M D, F A C P, David P Smith Clinical Professor of Medicine, Yale University School of Medicine, Consulting Physician to the New Haven Hospital *Volume I Anatomy and Physiology as Applied to Practical Medicine* Associate Editors HARRY BURR FERRIS, B A, M D, E K, Hunt Professor of Anatomy, Yale University School of Medicine, and HOWARD W HAGGARD, M D, Associate Professor of Applied Physiology, Sheffield Scientific School, Yale University xlv + 1271 pages, 344 illustrations *Volume II The Technic of Clinical Medicine* Associate Editor, JOHN T KING, JR, A B, M D, F A C P, Associate in Clinical Medicine, Johns Hopkins University School of Medicine xli + 984 pages, 227 illustrations 1932 D Appleton and Company, New York and London Price \$10 00 a volume

The two volumes under review are the first to be issued in The Practitioners Library of Medicine and Surgery. The entire set will consist of twelve volumes of which the last will be a composite index. Although each volume covers a unit area in the field of medical practice the entire set is so correlated as to present all that the editorial staff considers fundamental and essential. There are certain objections that are currently urged against such encyclopediac systems of medical practice, such as that they soon become out of date and that, after all, the very point upon which one wishes information is seldom covered. These objections of necessity have something of truth in them. But carefully selected material brought up to date by those who are experienced in its practical applications is rarely set aside within a short period of time. No one expects a medical text to be a complete guide throughout a lifetime. Judged as a piece of laboratory equipment, such a set

as The Practitioners Library should be expected to depreciate, but the practitioner will find that the rate of depreciation to be charged off is very much less than that which he must apply to most of the mechanical aids which he puts in his garage and in his examining room. As to completeness, each of the more than two hundred contributors has been chosen for his special fitness for presenting his subject. That must be the chief earnest of inclusion of the essentials. Brief bibliographic lists at the end of each chapter direct the reader to the chief sources of more detailed information. This set is not planned for the medical teacher or investigator in close contact with a large medical library. Rather, as its title states, it is for the practitioner. For him such a work is nearly indispensable. It is quite impossible for him to surround himself with separate monographic works to cover the entire field of his work. Even if he has many of them at hand, he can have a working familiarity with but a few. Hence is evident the value of an elaborately indexed, well-considered presentation of the entire range of medical practice.

Volume I Anatomy and Physiology as Applied to Practical Medicine Seven chapters are devoted to anatomy and twenty to physiology. Any detailed consideration is impossible. The authoritative position of the authors responsible for the individual chapters is indicated by the fact that Davenport writes on Heredity, Blumer, on Constitutions, Eyster, on Physiology of the Circulation, Henderson, on Respiration, Best, on Pancreatic Function, Thomson and Collier, on the Endocrine Glands, Gay, on Infection and Immunity, and Karsner, on Inflammation, to mention but a few.

Volume II The Technic of Physical and Laboratory Examination in Clinical Medicine In twenty-seven chapters the methods of examination in clinical medicine from History Taking to Oral Diagnosis, are sys-

tematically presented by authors equally as eminent in their respective fields as those contributing to the first volume. Naturally, there is no occasion for giving detailed directions for all bacteriological and histopathological procedures, but those considerations which will best enable the practitioner to secure effective cooperation from the laboratory experts to whom he must occasionally appeal are fully set forth.

Each volume is indexed separately in anticipation of the final composite index. The format is practical, and well chosen illustrations are liberally used.

Clinical Roentgen Pathology of Thoracic Lesions, by WILLIAM H. MEYER, M.D., Professor of Roentgenology in the New York Post-Graduate Medical School of Columbia University, and Director of Roentgenology in the New York Post-Graduate Hospital. Octavo, 272 pages, 183 illustrations. Lea & Febiger Co., Philadelphia, 1932. Price \$6.00.

Rarely does one encounter a book written for specialists which is as valuable to the internist, the surgeon and to all those working in clinical medicine as this volume, the first of a series, each devoted to some major division of roentgenology. As the title indicates, the discussion is here limited to diseases of the thorax so that after an introductory resumé of general roentgenological principles, separate sections are devoted to diseases of the thoracic cage, special diseases of the respiratory system, lesions of the heart and pericardium, and the esophagus and subphrenic organs in relation to intrathoracic pathology. In general, the material of these sections is treated in a systematic manner using such subheadings as disturbances of development, inflammation, neoplasms, etc. In terse, lucid sentences the roentgenological features of each type of disease process are given together with sufficient information of a gross pathological nature to demonstrate the physical bases of the deviations in illumination and configuration observed. The utilization of a large number of illustrations makes the work essentially an atlas of this division of roentgenology. The many white-on-black line plates are strikingly effective both from the

straightforward simplicity of their execution and the superior press work in evidence. These complement and immeasurably aid the explanation of the many half-tone reproductions of roentgenograms, the latter being distinguished for their wealth of detail and delicacy of tonal gradation. Not the least among the many excellent features of this book is the detailed index giving the pages for the main discussion together with the pagination of all other important collateral developments. By this means the bulk of the volume has been maintained at a minimum, since repetition has been almost entirely avoided. Considering the compactness of the volume, it would appear that the publishers, in setting a price for the book, have anticipated a far more limited sale than it deserves; for all those having any contact whatever with roentgenological interpretation will find here a compendium of the most useful information.

A Hand-Book of Ocular Therapeutics. By SANFORD R. GIFFORD, M.A., M.D., F.A.C.S., Professor of Ophthalmology, Northwestern University Medical School, Chicago, Illinois, attending Ophthalmologist, Passavant Hospital, Wesley Memorial Hospital, Evanston Hospital. 272 pages, 36 engravings. Lea & Febiger, Philadelphia, 1932. Price, \$3.25.

This is an outstanding work done by a man whose wide clinical experience and intimate association with his father, Harold Gifford, have given him a firm basis for reliable opinion. The book deals with the various therapeutic measures in a clear concise manner, giving his personal clinical experiences where there are conflicting opinions. The more recent advances are discussed giving special technique and illustrations for procedures not yet commonly followed. The section devoted to anesthesia is complete and well illustrated. Drugs are discussed from the standpoint of preparation, properties and administration, and those most commonly used are listed in a convenient manner. The present status of tuberculin therapy is made clear. The preparation and dosage are listed. The uses of phototherapy, diathermy, and roentgen ray are well covered. Foreign protein is given

full consideration in the treatment of iritis and uveitis. The author is particularly enthusiastic in his treatment of gonorrheal ophthalmia by this method. It is doubtful, however, if other experienced clinicians will discard the use of mild silver-protein in this and other purulent ophthalmias. Copper stick is recommended for treatment of trachoma in the early stages. The book covers in condensed form a great amount of work in the field of ocular therapeutics. Adequate bibliographies are provided should the reader desire further information. The value of Dr Gifford's handbook is unquestionable and practically every ophthalmologist will find it useful.

CECIL LEPARD, M D

Recent Advances in Bacteriology and the Study of the Infections. By J HENRY DIBLE, M B (Glas), F R C P, Professor of Pathology in the University of Liverpool, Late Professor of Pathology in the University of London, and Professor of Pathology and Bacteriology in the Welsh National School of Medicine. Second edition. xi + 476 pages, 29 illustrations. P. Blakiston's Son and Co, Inc, Philadelphia, 1932. Price \$3 50.

Like many others of the Recent Advances Series, the member dealing with bacteriology has required a new edition although the former one has been out but three years. This is not to be wondered at for bacteriology, which some had come to look upon as a well-tilled, and all but exhausted, field, is rapidly developing aspects which, while not entirely new, are nevertheless setting off the new bacteriology rather definitely from the old. New sections on certain of the virus diseases, Brucella infections, the flocculation tests for syphilis, the Salmonella group, and antigenic structure have been required. Throughout, the text has been reworked in the light of the newer developments with special attention to the streptococcus group, bacterial variation, the bacteriophage, B C G, and specific soluble substances of the pneumococci and other bacteria. The author weighs the presumptions in regard to the Lubeck disaster and without drawing a fixed conclusion writes, "A slowly increasing body of evidence which supports Petroff's views

of the constitution of B C G make[s] it possible that some special conditions obtaining during the culture of the vaccine at Lubeck may have caused the emergence of a virulent strain." Nor is the above sentence quoted to call attention to the ungrammatical verb, for the book is unusually free from errors in agreement and in typography. Rather was it quoted with approval as indicating a conservative attitude of quasi-acceptance of a view generally unpopular. This book can be heartily recommended to every practitioner of medicine who must keep informed of the rapid transformation in bacteriology but who obviously cannot seek this widely disseminated information out for himself from the original sources. It is also an invaluable reference book for medical libraries of all types, whether in teaching institutions or hospitals.

Functional Disorders of the Gastrointestinal Tract. By WILLIAM GERRY MORGAN, M D, F A C P, Professor of Gastroenterology, Georgetown University Medical School, Consulting Physician, Georgetown University Hospital, Garfield Memorial Hospital, and Gallinger Hospital, Washington, D C. xii + 259 pages, 32 illustrations. 1931, J B Lippincott Company, Philadelphia and London. Price \$5 00.

This concise, practical manual of gastrointestinal functional disorders is a unit in the Everyday Practice Series which is being brought out under the Editorship of Harlow Brooks, M D, F A C P. It is covered with the attractive *fac simile* antique binding characteristic of this series. Gastrointestinal disorders with demonstrable tissue changes are excluded from the scope of this manual, yet the so-called "functional" diseases play such a large part in everyday medical practice that a work devoted entirely to them is amply justified. In the words of the distinguished editor of this series, "This little book is designed especially to consider these disturbances of the gastrointestinal tract in such a manner as to make their recognition and proper management plain and clear. The book has been prepared by a practitioner widely known especially for his therapeutic skill in the management of cases of diseases of the gastrointestinal

tract" Numerous citations of illustrative cases and full discussions of treatment add to the interest and value This book deserves a wide circulation

Varicose Veins with Special Reference to the Injection Treatment By H O McPHEETER, M D, F A C S, Director of the Varicose Vein and Ulcer Clinic, Minneapolis General Hospital, Attending Physician New Asbury, Fairview, and Northwestern Hospitals, Minneapolis, Minn Third revised and enlarged edition 285 pages, 62 illustrations F A Davis Company, Philadelphia, 1931 Price \$4 00

For this third edition of McPheeter's work on Varicose Veins various sections

have been rewritten and considerable new material added While intended particularly as a guide to the treatment of this condition by the injection method and therefore giving considerable space to the essential technical details, there are a number of subjects discussed which are of interest to the general practitioner and to the internist Such are etiology, the reasons for the comparative rarity of pulmonary infarctions following the induction of thrombosis, coincident vascular complications, the management of varicose ulcer and the elephantoid condition of the lower leg due to lymphatic obstruction The book is well written, well illustrated and well printed

College News Notes

MINUTES OF THE BOARD OF REGENTS

San Francisco, Calif

April 4, 1932

(The following items are abstracted from the official minutes)

The Board of Regents of the American College of Physicians met and was called to order at the Palace Hotel, San Francisco, Calif, at 11 00 A M, by the President, Dr S Marx White, Minneapolis, Minn

The following were present Dr S Marx White, Dr James R Arneill, Dr David P Barr, Dr Walter L Bierring, Dr George E Brown, Dr James B Herrick, Dr Charles G Jennings, Dr Clement R Jones, Dr Noble W Jones, Dr J C Meakins, Dr James H Means, Dr John H Musser, Dr George Morris Piersol, Dr Maurice C Pincoffs, Dr Francis M Pottenger, Dr W Blair Stewart, and Mr E R Loveland, Executive Secretary

President White spoke briefly concerning the completed arrangements for the meeting He expressed the opinion that the subject of the next meeting place should be carefully studied, and that the meeting for 1933 should be held in a center which would attract a large attendance

The Executive Secretary read abstracted Minutes of the last meeting of the Board of Regents, which were approved as read

The Executive Secretary read the following excerpt from a letter addressed to President White from Dr Oswald T Avery

"Confirming my recent telegram, may I again tell you how deeply I appreciate the honor conferred on me by the American College of Physicians As the first recipient of the award, I feel particularly complimented, especially so since the recognition comes from a distinguished group of clinicians as an expression of their regard and appreciation of research in one of the allied sciences of medicine In giving this distinction to the work in which I have been privileged to share, I am conscious that in even larger measure they are paying a high tribute to the spirit and accomplishment of all who by observation and experiment are attempting to add to our knowledge of disease

"Thank you very much for your generous allotment of forty minutes for my address I feel, however, that I may be encroaching upon time that might more fittingly be given to others on the program In fulfilling the conditions of the award, I shall, of course, be happy to comply with your request, and on this occasion, if you so desire, suggest the following title for my remarks, 'The Rôle of Specific Carbohydrates in Pneumococcus Infection and Immunity'"

Resignations of the following were duly accepted

Dr William Willis Anderson (Fellow), Atlanta, Ga
 Dr L R DeBuys (Fellow), New Orleans, La
 Dr Rufus T Dorsey (Fellow), Atlanta, Ga
 Dr G C Kilpatrick (Fellow) Mobile, Ala
 Dr William Magner (Fellow), Toronto, Ont, Can
 Dr Leon F Shackell (Fellow), New Brunswick, N J
 Dr Stewart H Welch (Fellow), Birmingham, Ala
 Dr George S C Badger (Associate), Boston, Mass
 Dr R Alexander Bate (Associate), Louisville, Ky
 Dr Jeter C Bradley (Associate), Washington, D C
 Dr Stephen Cahana (Associate), Milwaukee, Wis
 Dr L E Elliott (Associate), New Market, Iowa
 Dr Thomas A Foster (Associate), Portland, Maine
 Dr Joseph M Heller (Associate), Washington, D C
 Dr Albert Kaufman (Associate), Wilkes-Barre, Pa
 Dr John D Matz (Associate), Allentown, Pa
 Dr David N Schaffer (Associate), Chicago, Ill

In reply to an inquiry concerning the collection of dues for 1932, the Executive Secretary reported that he had distributed a letter with all bills on Jan 1, suggesting that any one who found it impossible to pay his dues promptly might arrange through the Executive Offices for temporary deferment, or payment in monthly installments of said dues. Many letters of appreciation had been received from members, and, undoubtedly, a number of resignations were avoided.

Upon recommendation of the Committee on Credentials the following physicians were elected to Fellowship

Allen, William Herschel, Fort Sam Houston, Texas

Amberson, J Burns, Jr, New York, N Y
 Armstrong, Eugene Lawson, Los Angeles, Calif
 Ash, Wilfrid Anthony, Seattle, Wash
 Baltzan, David M, Sashatoon, Sask, Can
 Barnhart, Grant Samuel, Washington, D C
 Benson, Robert Louis, Portland, Ore
 Brooksher, William Riley, Jr, Fort Smith, Ark
 Brown, Robert Osgood, Santa Fé, N M
 Callaway, Guy Drennan, Springfield, Mo
 Carbonell, Arturo, Manila, P I
 Carley, Paul Sterling, New York, N Y
 Cassel, Homer Deeter, Dayton, Ohio
 Cohen, Mortimer, Pittsburgh, Pa
 Cole, William, Long Beach, Calif
 Comstock, Daniel Delos, Los Angeles, Calif
 Cook, Everett LeCompte, Denver, Colo
 Cornell, Virgil Heath, Washington, D C
 Cowie, David Murray, Ann Arbor, Mich
 Crawford, Paul Miller, Denver, Colo
 Curtis, Arthur Covell, Ann Arbor, Mich
 Dart, Raymond Osborne, Ancon, C Z
 Davis, Jay Conger, Minneapolis, Minn
 Davis, Robert Gaylord, San Diego, Calif
 Denton, William, Hot Springs Nat'n Park, Ark
 Faust, Daniel Bascom, San Francisco, Calif
 Gardam, Joseph William, Newark, N J
 Grant, Brooks Collins, Fort Sam Houston, Texas
 Greenbaum, Sigmund S, Philadelphia, Pa
 Gregg, Donald, Wellesley, Mass
 Guardia, Tomas Guardia, Panama, R. P
 Haines, Edgar Fremont, Washington, D C
 Henderson, George Dallas, Holyoke, Mass
 Hill, Harold Phillips, San Francisco, Calif
 Howard, Leroy Taylor, Fort Sam Houston, Texas
 Hudson, Fredrick Edward, Stamford, Texas
 Hyland, Clarence Michael, Los Angeles, Calif
 Kern, Richard Arminius, Philadelphia, Pa

La Barge, Oza Joseph, Salt Lake City, Utah
 Ledbetter, Paul Veal, Houston, Texas
 Lowry, Robert Henry, Fort Sam Houston, Texas
 Lutterloh, Charles Hartzell, Hot Springs Nat'l Park, Ark
 Madigan, Patrick Sarsfield, Washington, D C
 McKie, Alva Burton, Manila, P I
 Mebane, Douglas Hamilton, El Paso, Texas
 Moffitt, Herbert Charles, San Francisco, Calif
 Newcomb, Warner Hames, Jacksonville, Ill
 Noble, Mary Riggs, Harrisburg, Pa
 Oginsky, Maxim Alexander, Saratoga Springs, N Y
 Olch, Benedict, Dayton, Ohio
 Olmsted, Bertram Henry, San Francisco, Calif
 Otto, Frank Wesley, Los Angeles, Calif
 Perlberg, Harry James, Jersey City, N J
 Pinner, Max, Tucson, Ariz
 Pollock, William Cramer, Denver, Colo
 Quickel, Herbert Lee, Denver, Colo
 Rawls, William Bryant, New York, N Y
 Rice, William Frederick, San Francisco, Calif
 Roberts, Frank Lester, Trenton, Tenn
 Robeson, David Loran, Fort Monroe, Va
 Ross, William Hugh, Brentwood, N Y
 Rothschild, Karl, New Brunswick, N J
 Ridsill, Hillyer, Jr, Charleston, S C
 Ruschhaupt, Louis F, Milwaukee, Wis
 Rush, Homer P, Portland, Ore
 Sale, Charles Wallace, Fort Sill, Okla
 Schumacher, Irwin Clement, San Francisco, Calif
 Sellers, Erle Dees, Abilene, Texas
 Schroeder, William F, Rock Island, Ill
 Sloan, Andrew, Utica, N Y
 Sweany, Henry Claris, Chicago, Ill
 Traynor, Raymond Leo, Omaha, Nebr
 Van Valzah, Shannon Laurie, Denver, Colo
 Waldbott, George L, Detroit, Mich
 Wchenkel, Albert Michael, Detroit, Mich
 Weis, Clifford Robert, Dayton, Ohio
 Wetterberg, Louis F, Woodbridge, N J

White, Samuel Augustus, Fort Benning, Ga
 Wile, Udo Julius, Ann Arbor, Mich
 Withers, Sanford Martin, Denver, Colo
 Woodland, John C, Ancon, C Z
 Woodson, Thomas D, Washington, D C

Dr Stewart, a member of the Committee on Insignia, of which Dr Edgar Erskine Hume is Chairman, gave the following report

"Our Committee will have to ask for further time for our final and complete report on the matter of academic dress. The reason for this is that the whole subject is coming up for reconsideration in Great Britain and also in the United States. I have been in touch with some of those who take particular interest in this subject, and am told that it would be wise for the American College of Physicians to wait until after June 1 to make a decision, as otherwise it might become desirable later to make a change. If other American academic and scientific bodies, as well as universities, are to reconsider all this, we should, I believe, await their report before making ours."

(Signed) Edgar Erskine Hume, Chairman

It was regularly moved and seconded that the above report be approved and placed on file

APRIL 6, 1932

The Board of Regents of the American College of Physicians met and was called to order at the Palace Hotel, San Francisco, Calif, at 12 35 P M, by the President, Dr S Marx White, Minneapolis, Minn

The following were present: Dr S Marx White, Dr James R Arneill, Dr David P Barr, Dr Walter L Bierring, Dr George E Brown, Dr James B Herrick, Dr Charles G Jennings, Dr Clement R Jones, Dr Noble W Jones, Dr J C Meakins, Dr James H Means, Dr John H Musser, Dr George Morris Piersol, Dr Maurice C Pincoffs, Dr Francis H Pottenger, Dr W Blair Stewart, and Mr E R Loveland, Executive Secretary

The Executive Secretary read a letter from Dr S D Van Meter, Chairman of the Effort and Invitation Committee of the American Association for the Study of Gout, suggesting, first, that the American College of Physicians join other national

medical and surgical societies in extending an invitation for the Third International Gouter Conference to come to America in 1937, and, second, that the American College of Physicians appoint an official delegate to join the American delegation to the International Gouter Conference at Berne, Switzerland, at its next meeting to co-operate in bringing the International Gouter Conference to America in 1937

After discussion, on motion of Dr Biering, seconded by Dr Arneill, and regularly carried, it was

RESOLVED, that the Executive Committee be empowered to appoint a delegate to represent the College at Berne, Switzerland, in connection with the meeting of the International Gouter Association without expense to the College

ASSOCIATES

On behalf of the Committee on Credentials, Dr Piersol presented the list of candidates recommended by the Board of Governors for election to Associateship. The following physicians were duly elected

Alexander, Archibald Addison, Oakland, Calif

Arrendell, Cad Walder, Ponca City, Okla

Baer, Ridgely Waters, Frederick, Md

Ball, Ralph G, Manhattan, Kansas

Bell, John Kenner, Detroit, Mich

Blitch, Clifford G, Jacksonville, Fla

Bloom, Benson, Tucson, Ariz

Brand, Alonzo F, Fayetteville, N Y

Briskman, A Lee, Colorado Springs, Colo

Burkley, George Gregory, Rochester, Minn

Carman, Henry Franklin, Dallas, Texas

Carns, Marie L, Madison, Wis

Castell, Louis B, Washington, D C

Chernaik, Samuel Julius, New Britain, Conn

Chrisman, William Walter, Macon, Ga

Condry, Raphael Joseph, Elkins, W Va

Cronwell, Bernhard J, Jr, Austin, Minn

Deegan, John Kenneth, West Haven, Conn

Denison, Robert, Harrisburg, Pa

Durgin, Lawrence Newton, Amherst, Mass

Donnan, G, New Orleans, La

Esbenshade, John H, Lancaster, Pa
Fineman, Abraham Harold, New York, N Y

Flack, Russell Allen, LaFayette, Ind

Flipse, Mathew Jay, Miami, Fla

Foord, Alvin G, Pasadena, Calif

Fregeau, Aime N, San Francisco, Calif

Gardner, Walter P, St Paul, Minn

Goldbloom, A Allen, New York, N Y

Goldsmith, Leon A, Portland, Ore

Goldstein, Eli, New York, N Y

Gordon, Douglas M, Ponca City, Okla

Griffith, George Cupp, Philadelphia, Pa

Hannah, Wilham Sessions, Montgomery, Ala

Harding, George T, III, Columbus, Ohio

Hargrove, Marion Douglas, Shreveport, La

Harmeier, John Watson, Rochester, Minn

Harvey, James E, Pasadena, Calif

Hastings, Gordon, Little Rock, Ark

Hekimian, Ivan, Buffalo, N Y

Hiemstra, Wybren, Missoula, Mont

Hookey, John A, Sr, Detroit, Mich

Hunter, Melville Wallace, Monroe, La

Huntington, Herbert Arthur, Los Angeles, Calif

Ilsley, Morrill Leonard, Claremont, Calif

Johnston, John M, Pittsburgh, Pa

Kirby, Dunne Wilson, Philadelphia, Pa

Kramer, Louis Irving, Providence, R I

Lane, Lowell L, Philadelphia, Pa

Lawson, Herman A, Providence, R I

Lee, Russel Van Arsdale, Palo Alto, Calif

Lervy, Frank E, Philadelphia, Pa

Levin, Charles Morris, Richmond Hill, N Y

Lewis, Paul John, Yakima, Wash

Lichty, John Max, Pittsburgh, Pa

Markel, Albert G, Paterson, N J

McLain, Ernest K, Louisville, Ky

Menard, Olive Joseph, Boston, Mass

Milstead, Laurence C, Allentown, Pa

Mitchell, Louis Albert, Newark, Ohio

Murphey, Bradford J, Colorado Springs, Colo

Nakada, James Robert, St Louis, Mo

Norris, Henry Martin, East Orange, N J

Nussbaum, Sydney, Brooklyn, N Y

Osgood, Carroll W, Milwaukee, Wis

Pratt, Orlyn Bernard, Los Angeles, Calif

Reed, Marjorie E, Plymouth, Pa
 Safarik, Lumir Robert, Denver, Colo
 Scott, Roy L, Buffalo, N Y
 Scott, Walter Roger, Niagara Falls, N Y
 Sears, Thad P, Denver, Colo
 Sexton, Daniel Leritz, St Louis, Mo
 Shaw, John A, Fayetteville, N C
 Sheehan, George A, Brooklyn, N Y
 Simons, Samuel Shirk, Lancaster, Pa
 Spannuth, John R, Reading, Pa
 Squires, Willard Haywood, New York, N Y

Stallings, Walker Eugene, Boise, Idaho
 Taylor, James Edwin Campbell, Rochester, Minn

Terrell, Caleb O, Fort Worth, Texas
 Weisler, Harry, Brooklyn, N Y
 Werner, August A, St Louis, Mo
 Wilson, James Alfred, Meriden, Conn
 Ylvisaker, Lauritz S, Newark, N J
 Ylvisaker, Ragnvald S, Minneapolis, Minn

Dr Pierson stated that no doubt there would be a question in the minds of some of the Regents as to why some candidates whose names had been proposed for Fellowship appeared on the list of Associateship candidates. The reason for this was that according to the present By-Laws, all candidates proposed after the 31st of December, 1931, must be considered first for Associateship, and serve the three to five year period before they are eligible for proposal to Fellowship, except in the case of men of great prominence and distinction, who can, by order of the Board of Regents, be elected as Fellows. In some instances, men who were just elected to Associateship last year were proposed for Fellowship this year. Such men are not eligible for election to Fellowship, because they must remain Associates for at least three years before they are eligible to be proposed for Fellowship.

The Executive Secretary presented the report on the Committee on Exhibit at the Chicago Century of Progress in 1933 as follows:

"Your Committee consisting of Dr Clement R Jones, Dr James G Carr, and Mr E R Loveland, appointed to study the advisability of an exhibit by the College at the coming exposition in Chicago, in 1933, desires to submit the following report:

"The Committee met at Rochester on Feb-

ruary 13 and spent several hours in conversation and discussion with Dr T E Finnegan, Director of Educational Films for the Eastman Kodak Company, Mr Edwards, the production manager, and Dr Jones, the scenario writer. After considerable discussion the following plan was the only one which we felt could be recommended. This plan included the use of 1½ or 2 reels which would require some twenty to thirty minutes for each complete exhibition. One reel would be designed to present in motion pictures a complete physical examination, including the estimation of the blood pressure, a urine examination, a complete blood examination, and the taking of blood for a Wassermann test.

"The design was that the first reel or the first portion of the motion picture would present the physical examination as it ought to be done by any capable general practitioner, this to be followed by a further demonstration of special methods of examination regularly used by the specialist in internal medicine.

"For instance, if the routine physical examination suggested some question about the heart, the use of chest plates, of the electrocardiograph, and of the basal metabolimeter would be indicated, if the original examination raised a question as to disease of the gastro-intestinal tract, the x-ray, gastric analysis, stool analysis, gall bladder visualization and other allied procedures might be shown on the screen. It was planned that the second reel should include roentgenology as applied to the various problems of internal medicine, the electrocardiograph, and the basal metabolimeter, laboratory tests as related to the gastro-intestinal functions, to the gall bladder and to the blood and urine, special examination of blood for nitrogenous end-products, uric acid, bile pigments, etc. It would be our purpose to present to the public these various methods of special investigation with a view to instruction as to the importance of this special equipment and particularly as to the necessity for expert guidance of all these procedures and an interpretation of the results based on the experience and scientific training of the diagnostician.

"The cost of the reels alone is likely to be in the neighborhood of \$10,000. It is probable, so we gathered from the conversation, that the motion pictures might be procured for less than this. It is also possible that they might cost more. To this must be added, if such an exhibit is undertaken, a sum for retaining one or two young men to operate the machine. It is likely that two medical students might be found for this, each for half-time work. There might be in addition some expense for unexpected repairs. The members of the Committee feel that \$10,000 is probably a

minimum figure for the expense of such an exhibit

"We have outlined a plan of procedure which might be followed if the Regents deem it advisable. However, the members of the Committee are unanimous in the opinion that the expense of such an exhibit would not be justified by the results. We all feel that in order to keep the exhibit within anything like reasonable cost the demonstration must be shortened until its value would become very questionable and our feeling is that it would be unwise for the College to undertake the exhibit proposed above."

On motion, seconded and regularly carried, it was **RESOLVED**, that the report of the Committee be approved

On behalf of the Committee on Public Relations, Dr Jennings submitted the following report

"The Committee on Public Relations has considered the report of the sub-committee on Medical Education of the Committee on Medical Care for Children of the White House Conference on Child Health and Protection presented at the meeting of the section on medical service at Washington, D C, February 20, 1931

"The report deals extensively with the subject of Pediatric Education. Your committee recommends that the American College of Physicians heartily endorse the recommendations embodied in the report of the sub-committee on Medical Education, and express its appreciation for this able work in the interest of Pediatric Education."

On motion by Dr C R Jones, seconded by Dr Musser, and regularly carried, it was **RESOLVED**, that the report of the Committee on Public Relations be and is herewith approved by the Board of Regents

Dr Pincoffs suggested that the Committee on Public Relations should have access to the editorial pages of the *ANNALS* to make public their endorsement of this work of the National Committee, if they so wish. He expressed the opinion that the Public Relations Committee would do well, instead of leaving their conclusions to be more or less buried in the Minutes of our meeting, to use the editorial pages as a means of putting before the whole College and the general medical public, the results of their investigations

The Executive Secretary reported that he had been instructed to consult counsel concerning the possibility of restraining the

Pilgren Company from using the name of the American College of Physicians in their advertising with relation to a booklet "by the late Professor E S Bishop, M D, Fellow, American College of Physicians, and Professor of Clinical Medicine" Counsel advised that since the Pilgren Company had now agreed to refer to Dr Bishop, who actually was a Fellow of the College, as the "late" Professor Bishop, no further restraint could be enforced

No action was taken by the Board of Regents on the above

The Executive Secretary presented a list of Fellows and Associates whom he recommended be dropped from the rolls, because of more than two years' delinquency, as provided in the By-Laws, the list having previously been submitted to the Board of Governors

On motion by Dr Piersol, seconded by Dr Arneill, and regularly carried, it was

RESOLVED, that the delinquent members be dropped from the rolls of the College

In reply to an inquiry, the Executive Secretary made the following membership report

Masters	5
Fellows	2286
Associates	572
Total	2863

The Executive Secretary presented the financial reports of the College for the year ended December 31, 1931, and the proposed budgets for 1932. In summarizing the financial operation of the College for 1931, he pointed out that the Endowment Fund now amounts to \$52,400 and the General Fund to \$57,166 71, or a total of \$109,566 71, whereas on January 1, 1927, the total assets were less than \$10,000

The Treasurer, Dr Clement R. Jones, commented on the work of the Treasurer's Office for the past year, and reported that \$2,325 44 additional had been paid by one of the closed banks, and that it seemed very probable that all the funds of the College in closed banks would be paid in full, and that the Exchange National Bank, in which the College had some \$5,000, would likely open for business again very soon

On behalf of the Finance Committee, Dr Jones presented the following resolution to be referred to the Committee on Constitution and By-Laws for report at the next meeting of the Board

"That, within one month after installation, the President shall appoint a Finance Committee of three from the Board of Regents, which shall be authorized to have general supervision of the finances of the College, to select banks and trust companies as depositories for all College funds, after careful investigation as to the standing and reliability of such institutions. Said Committee shall have the power to authorize such banks to receive and pay money out of College funds upon the signature of the Treasurer or some Regent authorized by the Finance Committee, to invest the surplus and endowment funds of the College in such bonds as are approved for savings banks and estate trusts in Pennsylvania and New York, or other states with equal requirements

"The Executive Secretary shall make a monthly report to the Finance Committee of all receipts and disbursements for the preceding month, and at least sixty days before the Annual Meeting the proposed budget for the coming year shall be submitted to the Finance Committee for consideration and recommendation at the Annual Meeting of the Board of Regents. All matters affecting the financial welfare of the College shall be referred to this Committee for consideration and report to the Board of Regents. The Finance Committee shall, at least thirty days before the Annual Meeting, submit to the Executive Secretary an Annual Report for submission to the Board of Regents of all moneys and investments and shall report at any other time when called upon by the Board of Regents or the Executive Committee. The Treasurer shall be ex officio a member of the Committee"

After considerable discussion, on motion by Dr Bierring, seconded by Dr Jennings, and regularly carried, it was

RESOLVED, that the report of the Treasurer be received and that the proposed resolution be referred to the Committee on Constitution and By-Laws for a report at the next meeting

Discussion followed regarding the continuance of the present Finance Committee. It was suggested that the present Committee be continued, with Dr S Marx White substituted for the term of Dr Pottenger, President-Elect

On motion by Dr Pottenger, duly seconded and regularly carried, it was

RESOLVED, that the Finance Committee for the coming year shall consist of Dr Clement R Jones, Chairman, Dr Charles G Jennings (1933), Dr James S McLester (1934), Dr S Marx White (1935), and Dr Charles F Martin (1936)

On motion by Dr Pottenger, seconded by Dr Meakins, and regularly carried, it was

RESOLVED, that the Finance Committee, at the next meeting of the Board of Regents, recommend certain banks as depositories, and that a resolution be passed delegating the banks recommended, to act as depositories, and also that the Finance Committee recommend who shall sign checks

The Executive Secretary read the report of the Committee on Constitution and By-Laws, which was as follows

"The Committee on Constitution and By-Laws at the request of President S Marx White, who suggested the desirability of Honorary Fellowships in the College, submits the following

Suggested Amendments to Constitution

"1 Add to Article III, Section 3, paragraph 1, after the word 'elect' in the second sentence the words 'Honorary Fellow and'

"2 Article IV, first paragraph Add after the word 'Masters' the following 'There shall also be (c) "Honorary Fellows" as subsequently defined'

"3 Article IV, following the sixth paragraph '(c) Honorary Fellows Upon nomination of the Board of Regents the College may elect medical men or women or scientists engaged in medical research to be Honorary Fellows Such Honorary Fellows shall have all the privileges of members excepting the right of holding office or voting They shall not pay dues nor receive the publications of the College or other similar prerequisites granted to members paying dues'

Dr Stewart stated he doubted the advisability of enacting this change, and that the general sentiment of the Committee on Constitution and By-Laws was not favorable to the adoption of the change

On motion of Dr Jennings, seconded by Dr Pincoffs, and regularly carried, it was

RESOLVED, that the report of the Committee on Constitution and By-Laws be received and that recommendations in it be deferred

It was recommended by Dr Stewart that the resignation of Dr William H Deaderick as Governor of the State of Arkansas be accepted, due to the illness of Dr Deaderick

On motion by Dr Jennings, seconded by Dr Pincoffs, and regularly carried, it was

RESOLVED, that the resignation of Dr William H Deaderick as a member of the Board of Governors be accepted

On motion by Dr Pincoffs, seconded by Dr Bierring, and regularly carried, it was

RESOLVED, that the present Committee on ANNALS OF INTERNAL MEDICINE be continued until permanent arrangements are made for a standing Committee on the journal

Dr Stewart stated that three or four of the officials in the College had recommended that the Editor of the ANNALS should be made an ex officio member of the Board of Regents, and that the Committee on Annals would be glad to co-operate with whatever action the Board desired

On motion by Dr Pincoffs, seconded by Dr Musser, and regularly carried, it was

RESOLVED, that the matter of the Editor of the ANNALS being made an ex officio member of the Board of Regents be referred to the Committee on Constitution and By-Laws

The Executive Secretary announced that very cordial and complete formal invitations had been received from the cities of Pittsburgh, Chicago, Montreal and Indianapolis to hold the next Convention of the American College of Physicians in those cities

Dr Herrick, on behalf of Chicago, presented invitations from the Deans of the University of Chicago and Rush Medical College, Northwestern University Medical College, University of Illinois Medical College and Loyola University Medical College, likewise letters from Dr A R Elliott, from the Chicago Medical Society, Illinois State Medical Society and the Chicago Association of Commerce

Dr Meakins stated that Dr Martin, one of the former Presidents, had for some time been keen to have the College meet in Montreal and that they had decided to wait until it could be done properly, that he now had with him an invitation from Dr Martin and from the two Universities of Mon-

treál and the medical schools and hospitals, to hold the 1933 Clinical Session in Montreal

Dr Clement R Jones presented in detail the advantages of meeting in Pittsburgh. It was the consensus of opinion that the 1933 meeting should be held near the center of population. Dr Meakins stated that while the invitation from Montreal was for 1933 that they would be just as happy to have the meeting there in 1934, if the other members felt it would be more satisfactory to have the 1933 meeting in the United States. After considerable discussion, it was decided to defer decision as to the next meeting place until the next meeting of the Board of Regents

Adjournment

APRIL 8, 1932

The Board of Regents of the American College of Physicians met and was called to order at the Palace Hotel, San Francisco, Calif, at 12 45 P M, by the President, Dr Francis M Pottenger, Monrovia, Calif

The following were present: Dr Francis M Pottenger, Dr James R Arneill, Dr David P Barr, Dr Walter D Biering, Dr George E Brown, Dr Charles G Jennings, Dr Clement R Jones, Dr Noble W Jones, Dr J C Meakins, Dr James H Means, Dr George Morris Piersol, Dr Maurice C Pincoffs, Dr W Blair Stewart, Dr S Marx White, and Mr E R Loveland, Executive Secretary

The Executive Secretary read an abstract of the Minutes of the last meeting, which was approved as read

After discussion regarding the standing Committee on ANNALS, on motion by Dr White, duly seconded and regularly carried, it was

RESOLVED, that a standing Committee on ANNALS OF INTERNAL MEDICINE be constituted to consist of three members to be appointed by the President—one for a term of one year, one for a term of two years, and one for a term of three years, and, thereafter, at the expiration of the term of each member, the President shall appoint his successor for a period of three years

There was a discussion of having a permanent Committee on Constitution and By-

Laws, whereupon on motion by Dr White, seconded by Dr Means, and regularly carried, it was

RESOLVED, that a standing Committee on Constitution and By-Laws be constituted—the President to appoint one member for one year, one member for two years, and one member for three years, and, thereafter, annually, the President, upon assuming office, shall appoint a member to succeed each member as his term expires

On motion by Dr White, seconded by Dr Piersol, and regularly carried, it was

RESOLVED, that the Executive Committee be re-elected, with the addition of Dr Walter L. Bierring to fill the place left vacant by the death of Dr Aldred Scott Warthin

The following members were therefore designated to serve on the Executive Committee Dr Francis M. Pottenger, Dr Clement R. Jones, Dr Walter L. Bierring, Dr J. C. Meakins, Dr James H. Means, Dr James Alex. Miller, Dr George Morris Piersol, Dr Maurice C. Pincoffs and Dr S. Marx White

Nominations for Secretary General were made as follows Dr William Gerry Morgan, Washington, D. C., nominated by Dr White, seconded by Dr Piersol, Dr William D. Stroud, Philadelphia, Pa., nominated by Dr Means, and duly seconded. Voting was done by ballot. The tellers, after making their count, reported Dr Morgan's election.

It was moved, seconded and regularly carried, that Dr Morgan's election be made unanimous.

Upon nomination and unanimous vote, Dr Elmer H. Funk, Philadelphia, Pa., was elected Treasurer.

Free discussion as to the next meeting place followed. It was decided that it was a matter for the Board of Regents to take action upon, and that a vote should be taken to determine the question.

The result of the voting was Chicago, 1, Pittsburgh, 3, and Montreal, 9.

Dr Jonathan C. Meakins was unanimously appointed General Chairman. It was suggested that the time of the meeting be set for some week in February, according to

the convenience of Dr Meakins and his Montreal committees.

A discussion followed concerning financial procedures in the College. Upon motion regularly made, seconded and carried, it was

RESOLVED, that the depositories for the College funds be the present depositories, the First National Bank of Pittsburgh, the Colonial Trust Company of Pittsburgh, Union National Bank of Pittsburgh, Commonwealth Trust Company of Pittsburgh and an additional bank or banks selected in Philadelphia or New York after investigation by the Finance Committee.

Dr C. R. Jones, Chairman of the Finance Committee, brought up the subject of having someone in addition to the Treasurer and the Executive Secretary authorized to sign either vouchers or checks, in case of the incapacity of either the Treasurer or Executive Secretary.

Upon motion by Dr C. R. Jones, seconded by Dr White, and regularly carried, it was

RESOLVED, that the Board of Regents empower the Chairman and the Vice Chairman of the Finance Committee to sign checks and/or vouchers for College funds, so that in case of incapacity of the Treasurer and/or Executive Secretary such funds would not be tied up.

On further motion by Dr White, seconded by Dr Stewart, and regularly carried, it was

RESOLVED, that the ex-Treasurer, Dr Clement R. Jones, be empowered to sign checks until such time as the transfer of funds is made to the new Treasurer and recorded.

Dr Clement R. Jones extended an invitation to the American College of Physicians to meet in Pittsburgh in 1934. He stated that Pittsburgh would continue preparing for the College, and that the College would not be disappointed when it finally selected Pittsburgh.

In answer to the question as to whether an Associate automatically becomes a Fellow, under the new plan, it was explained that inasmuch as the credentials or qualifications of a candidate change between the time of his election to Associateship and the time he may be proposed for Fellowship, the

Committee feels it desirable to have him re-proposed on the regular form for advancement to Fellowship at the proper time. He can be re-proposed by any Fellow of the College, seconded by another Fellow and endorsed by an Officer, Regent or Governor. The By-Laws provide that at the expiration of three years, Associates shall be notified in writing of their eligibility for proposal for

election to Fellowship within the next two years, providing they shall meet within that time the requirements necessary for Fellowship.

There being no further business, the meeting adjourned at 2 15 P M

E R LOVELAND,
Executive Secretary

MINUTES OF THE BOARD OF GOVERNORS SAN FRANCISCO, CALIF., APRIL 4, 1932

(Abstracted from the official minutes)

The Board of Governors of the American College of Physicians met and was called to order at the Palace Hotel, San Francisco, California, at 4 15 P M, by the Chairman, Dr W Blair Stewart, Atlantic City, New Jersey.

The following were present: Dr W Blair Stewart, Dr Ernest B Bradley, Dr Charles H Cocke, Dr T Homer Coffen, Dr A Comingo Griffith, Dr Josiah N Hall, Dr Thomas Tallman Holt, Dr Hans Lisser, Dr William Gerry Morgan, Dr G G Richards, Dr Adolph Sachs, Dr Rock Sleyster, Dr Charles T Stone, and Mr E R Loveland, Executive Secretary.

The Executive Secretary read abstracted minutes of the last meeting of the Board of Governors, which were approved as read.

Dr Stewart introduced Dr Francis M Pottenger, President-Elect, who spoke briefly on the importance of the work of the Board of Governors and the ultimate goal of the College. He said the future of the College is to be determined very largely by the Board of Governors, that a great deal of responsibility lies with the Board of Governors in passing upon the qualifications of young men proposed for membership, to encourage young men who are capable and desirable by helping them along, but not to recommend a man simply because he desires membership. Dr Pottenger said that the following questions often arise: What is to be the future of our organization? What is its purpose? Shall we launch out into something more? What shall be our ultimate goal? His feeling was that we ought to take a firm stand

for Internal Medicine and all that it stands for, that we should be the greatest influence in America for Internal Medicine.

Chairman Stewart spoke briefly of his work as Chairman of the Board of Governors during the past year. He reported that the oldest member of the Board, Dr Edward O Otis, of New Hampshire, had asked to be kindly remembered to all members of the Board of Governors. Communications from other Governors who were unable to be present were also presented.

Upon request, the Executive Secretary read portions from the Constitution and By-Laws regarding requirements for admission to Associateship—especially those referring to the period of time a physician must be in active practice before he is eligible for proposal.

Upon request of Dr Stewart, President White, who had just entered the meeting at this time, spoke briefly regarding the increased responsibility of the Board of Governors since the amendments to the Constitution and By-Laws adopted at the Boston Session in 1929 had become effective on January 1, 1932, namely, that all new members must enter the College first as Associates, and that all candidates for Associateship are passed upon first by the Board of Governors. Dr White stated that these amendments had been incorporated in the Constitution and By-Laws because of the necessity for some mechanism by which there could be greater scrutiny and better opportunity for studying prospective Fellows of the College. The new arrangement provides that every physician in the future, except in very special cases, shall come in first

as an Associate, and shall be under the careful scrutiny of the Board of Governors and the Board of Regents for a period of three to five years before he shall be eligible for election to Fellowship. It will give the College a chance to study the physician in his relation to his profession, his responsibility, his attitude, his personality, etc.

President White further referred to another point of interest in the evolution of the College, as to whether the College should undertake functions which might be considered economic, that there will unquestionably be some drastic changes affecting medical economics, and that it is important to consider and discuss any participation the College may subsequently undertake.

Chairman Stewart read a letter and a telegram from Dr E J G Beardsley, Governor for eastern Pennsylvania, recommending that the College should elect a Governor for the State of Delaware.

Upon motion by Dr Richards, seconded by Dr Griffith, and regularly carried, it was

RESOLVED, that the Nominating Committee be requested to make a nomination for a Governor for the State of Delaware.

Dr C H Cocke, Vice-Chairman of the Committee on Credentials for Associateship, reported for that Committee in the absence of the Chairman, Dr Allen A Jones. The Committee recommended to the Board of Governors for their approval to the Board of Regents the election of 85 physicians. (A list of those recommended may be found in the minutes of the meeting of the Board of Regents for April 6, 1932.)

On motion by Dr Griffith, seconded by Dr Holt, and regularly carried, it was

RESOLVED, that the report of the Credentials Committee be received and that the candidates be recommended to the Board of Regents for election to Associateship.

The Executive Secretary then presented a list of twenty members delinquent in dues for more than two years. He stated that every possible means had been resorted to in order to collect the dues from these members, and that, as his last resort, he had notified them that they would be dropped from the rolls of the College at this meet-

ing, should their dues not be paid. This list represents those who have failed to comply with the requirements of the By-Laws, and are to be presented to the Board of Regents for being dropped for delinquency.

Upon inquiry from one of the members of the Board, Chairman Stewart explained the procedure that must be followed in order to drop an undesirable member. The By-Laws, Article XIII, Section 1, provides a method of expulsion.

Dr Lisser, Governor for northern California, suggested the desirability of sending a letter to the entire membership of Fellows, stating clearly that the College is not interested in number, but is distinctly interested in the quality of candidates, and suggesting that in the future Governors may not be put in the awkward position of being asked to endorse candidates whom they do not consider qualified for election. Dr Lisser also raised the question concerning the candidate who lives at such a distance that it is not possible for the Governor to meet or to know him personally. Chairman Stewart replied that it is, of course, desirable to contact each candidate, but if, because of distance, the Governor is not able to visit the candidate or have the candidate visit him, he should write to physicians, preferably members of the College, residing in the same community in which the candidate lives, inquiring specifically about the candidate's professional standing, medical ethics, and other relevant details helpful in determining the candidate's fitness for election.

Adjournment

APRIL 7, 1932

The Board of Governors of the American College of Physicians met and was called to order at the Palace Hotel, San Francisco, Calif., at 12 45 P M., by the Chairman, Dr W Blair Stewart, Atlantic City, N J.

The following were present: Dr W Blair Stewart, Dr Ernest B Bradley, Dr James G Carr, Dr Charles Hartwell Cocke, Dr T Homer Coffen, Dr A Comingo Griffith, Dr Josiah N Hall, Dr Thomas Tallman Holt, Dr Ernest E Laubaugh, Dr Hans Lisser, Dr Leander A Rely, Dr G

G Richards, Dr Adolph Sachs, Dr Charles T Stone, and Mr E R Loveland, Executive Secretary

The Executive Secretary presented the financial reports for the year ended December 31, 1931, and discussed them in detail

Chairman Stewart asked for expressions of opinion, individually or collectively, upon the question of where the next annual meeting of the College should be held. He reported that invitations had been received from Pittsburgh, Montreal, Chicago, Memphis and Indianapolis, and that while the meeting city would be selected by the Board of Regents, they would appreciate the recommendations of the Board of Governors. After discussion of present economic conditions, the ability of different cities extending invitations to provide necessary requirements for a Clinical Session of the College, etc, the consensus of opinion was that a central location should be selected, and that the invitations of Chicago and Pittsburgh be particularly considered.

Chairman Stewart stated that the San Francisco meeting had been one of the outstandingly successful gatherings of the College, and that much credit was due to members from San Francisco and California, generally.

On motion by Dr Cocke, seconded by Dr Bradley, and regularly carried, it was

RESOLVED, that the Board of Governors of the American College of Physicians express its appreciation and gratitude for a most excellent program given by the California men, and that this appreciation be extended particularly to Dr William J Kerr, General Chairman, and to his various Committees.

Chairman Stewart then expressed his appreciation and thanks to the members of the Board of Governors who had come to the meeting. He asked members of the Board always to bear in mind the desirability of raising the standard of the College a little higher than it was prior to the adoption of the amendments to the present Constitution and By-Laws, that Governors

should remember that while new candidates for Associateship are not required to present the qualifications for full Fellowship, no candidate should be endorsed unless he promises to qualify for Fellowship within a period of three to five years.

Dr Stewart thanked the Governors also for responding promptly to communications and inquiries from the Executive Secretary with regard to candidates, and asked them to co-operate in selecting from the Associates in the different districts those men who are eligible for proposal for Fellowship. While the College is not seeking large numbers, it is important to select from the list of Associates in the different states those men who possess outstanding qualifications and who will make good as Fellows.

On motion by Dr Bradley, duly seconded and regularly carried, it was

RESOLVED, that the Board of Governors express its appreciation of the work of the Executive Secretary, Mr Loveland.

Before adjournment, Dr Cocke, for the Committee on Credentials, requested all members of the Board to give earnest consideration to the recommendation of candidates, in an effort to assist the Committee in passing on men proposed for membership. He stated that the comments received about the same candidate are often widely different, that in many cases one Governor will heartily approve of a candidate and another Governor will have emphatic objections to the same man, making it very difficult for the Committee on Credentials to reach a decision concerning election. Dr Cocke also stated that many cards are returned stating that the candidate is "unknown", which emphasizes the need of having the Governor make thorough investigation through friends, acquaintances, or other members of the College, and to send such personal and definite information for the attention of the Committee.

Adjournment

E R LOVELAND,
Executive Secretary

GENERAL BUSINESS MEETING
OF THE
AMERICAN COLLEGE OF PHYSICIANS
SAN FRANCISCO, CALIF.,
APRIL 7, 1932

The General Business Meeting of the American College of Physicians, held in connection with the Sixteenth Annual Clinical Session in the Gold Ballroom of the Palace Hotel, San Francisco, Calif, convened at 4 45 P M, Thursday, April 7, 1932, Dr S Marx White presiding

Dr White said in part "This meeting in San Francisco has been one of the delightful experiences on the part of the members of the College. It has been a privilege to me to serve the College in the capacity of its presiding officer during the past year and have a part in the preparation of the program. This is the second meeting to use the new method of program-making by which the President makes up the national program, dividing the responsibility so that the General Chairman and the Local Committee make up the clinical program. San Francisco has given us one of the unique meetings. I was extremely anxious that during this meeting there should be an opportunity for the Fellows of the entire country to learn what 'our other metropolis' has to show."

The reading of the Minutes of the last meeting was dispensed with.

The Treasurer commented on his report which had been previously published in the *ANNAIS OF INTERNAL MEDICINE*. An interesting comparison of the finances of the organization was made. Dr Jones stated that at the time of taking over the office of Treasurer eleven years ago, there was about \$8,000 in the treasury, and that the amount in the treasury at the present time was around \$130,000. In retiring as Treasurer, Dr Jones expressed the hope that the finances would progress rapidly, and that the endowment fund might continue to increase and be sufficient to carry on such work as was done this year in presenting the John Phillips Memorial Prize. Dr Jones expressed his appreciation of the courtesies and considerations that had been shown him by the Fellows during the eleven years that he was Treasurer.

Upon motion, the report of the Treasurer was accepted.

The Executive Secretary presented his annual report, mentioning among other matters the publication of the 1931-32 Directory, with membership statistics, including 5 Masters, 2286 Fellows and 572 Associates, a total of 2863. He reported that there were twenty-eight Life Members, including the retiring President, Dr White, as the most recent one. He also reported that the registration at the Clinical Session was 1,586, of which 133 were visiting ladies. An invitation was extended to all members of the College to visit the headquarters at Philadelphia whenever they are in that City.

Dr John Dudley Dunham, Columbus, Ohio, proposed a rising vote of thanks, which was given, to the San Francisco members responsible for the splendid entertainment and magnificent program furnished.

Dr White said in part "Before relinquishing the chair, your President wants to outline one or two considerations which occurred to him during this year, and the year previous. The College has won a place in American medicine in the sixteen years of its activities. I feel strongly that the American Medical Association has its prime place in the professional and economic life of Medicine in this country, that there is a place, however, for other organizations with special interests, and a place which can be of extreme and extraordinary usefulness.

"Not only is there opportunity for professional advancement and for the study of the specific problems which a group like ours might desire to consider, in the interests of the type of work which we represent in American Medicine, but there is also an opportunity and a necessity for a study and discussion of some of the economic questions in Medicine. I have no desire to outline them at this time—I tried to outline them briefly in my address last night, but it seems to me that much as we should like to retain our clinical interests only, we will be re-

quired, through the years which are immediately ahead, to take some very definite part in the study and recommendations on economic problems. Just how that is to be brought about seems to be a very difficult matter for us to decide. I am thoroughly aware that pronouncements on economic questions in medicine are extremely difficult, our basis for understanding is different, the approach which each of us makes to various problems is so different. I think the ideals of all of us look very much in the same direction, and yet, economic considerations will be forced upon us, and only as we are in position to study them and at least to mark out what are safe and sane and effective approaches to our economic problem, can we expect to keep up with the rapid crystallization which is eventually coming to us in Medicine. How that is to be brought about, I have no recommendations to make, but this body as a whole, I feel, must be prepared and should be thinking strongly along lines other than the clinical one."

The retiring President, Dr. White, presented the incoming President, Dr. Francis

M. Pottenger, of Monrovia, Calif., who made the following remarks:

"I wish to thank you for this great honor you have conferred upon me. I never had any anticipation that I might be President of this organization. I have always worked for this organization. I have been on the Board of Counsellors and Regents since its inception. When it was brought to my notice in the beginning, I thought it was one of the greatest opportunities for Internal Medicine that had ever been offered in America, and I still think that is what we have. I have attended all the meetings since its organization, except one, and I have seen it grow in interest and in usefulness, ever feeling that this organization is fulfilling the wants of its members."

"I simply want to say to you that I will do my best. My predecessors have set a pace and I hope I can progress throughout my administration. I ask you all to help me."

In the absence of Dr. Stengel, Chairman of the Nominating Committee, Dr. Stewart submitted the following report:

"The Nominating Committee of the American College of Physicians begs to offer in nomination

For the Elective Offices

President-Elect
First Vice President
Second Vice President
Third Vice President

George Morris Piersol, Philadelphia, Pa.
Maurice C. Pincoffs, Baltimore, Md.
Charles G. Jennings, Detroit, Mich.
Noble Wiley Jones, Portland, Ore.

For the Board of Regents

(Term Expiring 1935)

Arthur R. Elliott
James B. Herrick
S. Marx White
David P. Barr
Clement R. Jones

Chicago, Ill.
Chicago, Ill.
Minneapolis, Minn.
St. Louis, Mo.
Pittsburgh, Pa.

For the Board of Governors

(Term Expiring 1935)

Egerton L. Crispin
Gerald B. Webb
Henry F. Stoll
William Gerry Morgan
Ernest E. Laubaugh
Samuel E. Munson
Robert M. Moore
Thomas Tallman Holt
Roger I. Lee
Adolph Sachs
Allen A. Jones
Leander A. Riely
Edward J. G. Beardsley
Edwin Bosworth McCready
John O. Manier

A resolution was regularly adopted, accepting the nominations and electing the nominees
Dr George Morris Piersol, President-Elect, spoke a few words of appreciation for the honor bestowed upon him

The meeting adjourned at 5 35 P. M

E R LOVELAND, Executive Secretary

Dr Hugh S Cumming (Fellow), Washington, D C, U S Public Health Service, has been reappointed and confirmed to the office of Surgeon General for another term of four years

Dr William Gerry Morgan (Fellow), Washington, D C, has been appointed a member of the Council from the District of Columbia of the Southern Medical Association, the reappointment having been announced recently by the President, Dr Lewis J Moorman (Fellow), Oklahoma City, Oklahoma

Dr Joseph Yampolsky (Fellow), Atlanta, Georgia, has been elected First Vice-President of the Fulton County Pediatric Society, for 1932

Dr William Stroud (Fellow), Philadelphia, Pa, professor of cardiology in the Graduate School of the University of Pennsylvania, gave a lecture in the Sunbury High School auditorium, January 19, on "The Presence of Heart Disease in Children"

Dr Paul D White (Fellow), Harvard Medical School, Boston, Mass, gave an address before the Richmond Academy of Medicine on February 9, his subject being "The Treatment of Cardiovascular Disease"

Dr White was also a visitor to the Medical College of Virginia this month, and gave a clinic for third and fourth year medical students

Dr James S McLester (Fellow), Birmingham, Ala, professor of medicine, Univer-

sity of Alabama, delivered the third annual Stuart McGuire Lecture of the Medical College of Virginia, Richmond, on the night of March 4 Dr McLester, a special investigator in the field of nutrition, spoke on "Nutrition in Its Newer Aspects"

Dr Jonathan C Meakins (Fellow), Montreal, Que, Canada, addressed the San Francisco County Medical Society, March 15, on "Treatment of Cardiac Irregularities"

Dr George Piness (Associate), Los Angeles, Calif, addressed the San Diego County Medical Society, March 8, on "Practical Application of Allergy in General Medicine"

Dr Louie M Limbaugh (Fellow), and Dr Thomas M Palmer (Associate), both of Jacksonville, Fla, participated in a symposium on the value of the Mantoux tuberculin reaction in the diagnosis of the childhood type of tuberculosis, held before a recent meeting of the Columbia County Medical Society

Dr William W Graves (Fellow), St Louis, Mo, addressed the Madison County Medical Society, March 4, at Alton on "Practical Basis in the Diagnosis of Neurologic Conditions"

Dr William F Lorenz (Fellow), Madison, Wis, presented a paper before the Chicago Neurological Society, March 17, on "Confessions Obtained During Narcosis"

Dr John H Musser (Fellow), New Orleans, La, addressed the East West Feliciana

Bi-Parish Medical Society in Jackson, February 3, on "Some Facts About Nutrition"

The fifth course of lectures under the William Sidney Thayer and Susan Read Thayer Lectureship in clinical medicine at Johns Hopkins Hospital, was given March 22-23, by Dr Alphonse R Dochez, professor of medicine, Columbia University College of Physicians and Surgeons, New York

Dr George B Eusterman (Fellow), Rochester, Minn, addressed the Wayne County Medical Society, Detroit, March 15, on "Incidence and Nature of Gastric Lesions Masquerading as Benign Disease"

Dr Adolph E Voegelin (Fellow), Detroit, Mich, recently delivered four lectures on cardiology at the Evangelical Deaconess Hospital

Dr Horace W Soper (Fellow), St Louis, Mo, spoke on "Diagnosis of Carcinoma of Colon" at the meeting of the St Louis Medical Society, February 23, 1932

Dr James Alexander Miller (Fellow), New York, was among the speakers at a meeting of the advisory council of the Milbank Memorial Fund, March 16-17. The council met in groups, in which discussions were held on health centers, health education and tuberculosis in children, population studies and public health nursing

Dr Cyrus C Sturgis (Fellow), Ann Arbor, Mich, addressed the Cleveland Academy of Medicine, March 18, on "The Outlook of the Patient with Pernicious Anemia"

Dr Charles W Burr (Fellow), Philadelphia, Pa, contributed to a program dedicated to the memory of Dr Charles K Mills, one of the founders of the Philadelphia Neurological Society, at a meeting of that organization held March 18

The following Fellows appeared on the fourth annual spring clinical conference

sponsored by the Dallas Southern Clinical Society, held at Dallas, March 28-April 2

Dr Thomas R Brown, Baltimore, Md—
"The Story of Digestion and Indigestion",

Dr Samuel A Levine, Boston, Mass—
"Bedside Recognition of Irregularities of the Heart",

Dr Williams McKim Marriott, St Louis, Mo—"Practical Points in the Care and Feeding of Infants"

Dr John E Walker (Fellow), Opelika, Ala, addressed the sixty-fifth annual session of the Medical Association of the State of Alabama, at Mobile, April 19-22. His subject was "Bacteriophage Its Nature and Therapeutic Application"

Dr George T Harding, Jr (Fellow), Columbus, Ohio, spoke before the Muskingum Academy of Medicine, Zanesville, March 2, his subject being "Intoxication Psychoses and Bromides"

Dr Cassius H Hofrichter (Associate), Medina, Wash, addressed the King County Medical Society, Seattle, March 7, on "Tooth Decay, Diet and Vitamins"

Dr Harry R Litchfield (Fellow), Brooklyn, N Y, conducted the Pediatric Pathological Conference at the Cumberland St Hospital of Brooklyn, March 30, 1932. At this conference he contributed a paper on "Congenital Syphilis"

Dr Louis Faugeres Bishop, Jr (Fellow), New York City, presented an example of congenital malformation of the aortic cusps, with detailed report, before the Society for Clinical Study, at its meeting on January 26, 1932

On March 22, 1932, Dr J Reid Broderick (Fellow), of Savannah, Georgia, addressed the Georgia Medical Society in Savannah on the subject, "Coronary Thrombosis and Angina Pectoris"

OBITUARIES

DR ELMER HENDRICKS FUNK

Dr Elmer Hendricks Funk (Fellow), Philadelphia, a much respected and admired clinician of the Quaker City's, so termed, "younger group" and a medical teacher and writer of rare individuality and charm, died suddenly of angina pectoris at his home in Overbrook, Pennsylvania, on May 13, 1932, aged 46 years

He was born, reared and educated in Philadelphia, being an honor graduate of the Jefferson Medical College in 1908, and having subsequently served the Jefferson Medical College Hospital, successively, as Resident Physician, Chief Resident Physician, Medical Director and Medical Director and Physician in Charge of the Department for Diseases of the Chest. He also served as Resident Physician in the Philadelphia Hospital for Contagious Diseases and at the White Haven Sanitarium for Tuberculosis

Dr. Funk inherited a pleasing and gracious personality and possessed a cheerful, unselfish and happy disposition. Early in his medical career the kindly Fates brought him into intimate contact with a select group of vigorous and inspiring personalities for whose names and traits all Philadelphians are justly proud. To mention but three of a much larger number whose wholesome influence would prove a decided stimulus to any medical man, even if he were far less gifted and brilliant in intellect than was Elmer Funk, will suffice. To have enjoyed frequent conferences with such sterling and altruistic characters as the late lamented Judge Meyer Sulzberger and the Hon-

orable William Potter or the, fortunately for Philadelphia and for the Jefferson Medical College and Hospital, still active and enthusiastic Alba B Johnson, was ideal training for a young man's mental and spiritual growth. To work early and intimately, for a period of years, with such excellent physicians as Hobart A Hare, F X Dercum, W M L Coplin, Randle C Rosenberger, J Parsons Schaeffer, Francis Stewart, Albert P. Brubaker, James C Wilson, S Solis-Cohen, Chevalier Jackson, E Quin Thornton, John H Gibbon, J Chalmers Da Costa, Thomas McCrae and similar practical idealists in the profession of medicine, is the traditional kind of training that tends to produce the high type of physician that Elmer Funk became. A little later in his life, fortunate chance brought about a professional intimacy with such inspiring men as Lawrence F Flick, James M Anders, Charles J Hatfield, Henry Page, H R. M Landis, George W. Norris, Arthur Newlin, Eugene Opie and Joseph Walsh. Elmer Funk was a fortunate youth to possess such professional colleagues and friends, and they were equally fortunate to work with such a whole-souled and appreciated junior associate.

Dr Funk became interested in medical teaching and writing even in his undergraduate medical student days, and he later served faithfully, brilliantly and helpfully as Demonstrator, Lecturer, Assistant Professor, Associate Professor and Clinical Professor of Medicine in his Alma Mater.

In September, 1931, Dr Funk was selected by unanimous vote of the

Board of Trustees of the Jefferson Medical College, to succeed the late Hobart A. Hare as Professor of Therapeutics in that century-old institution. Few medical men, in any age, have crowded as much of work, study, investigation, research, teaching, writing, lecturing, work for organized medicine and civic philanthropy as Dr. Funk accomplished in his too brief span of years into their lives.

Dr. Funk had an active part in many organizations and was, perhaps, best known for his intimate knowledge of diseases of the respiratory system. He was assistant editor of the third edition of the "Osler System of Medicine," and in 1930 published a book entitled, "The Diseases of the Respiratory Tract."

His interest in all phases of tuberculosis, and the active part that he played in the campaign against this disease, resulted in his frequently being termed "a tuberculosis specialist."

Dr. Funk became a Fellow of the American College of Physicians on April 1, 1923. At the recent Clinical Session of the College at San Francisco, he was unanimously selected as Treasurer. He was a member of the Council of the Association of American Physicians, for a number of years he had been the Recorder of this Association.

He was an admired and beloved member of the Interurban Medical Association, former President of the Pennsylvania Tuberculosis Association and an active worker in the Philadelphia Health Council. He was a past Vice Fellow of the American College of Physicians of Philadelphia, and a Consulting Physician to the Jefferson Hospital, the

Pennsylvania Hospital and White Haven Sanitarium. He was a fluent speaker, a teacher of exceptional talent and ability and a generous contributor of excellent papers to all medical publications. His premature death has robbed the medical profession of a forceful and useful member, and he will long be lovingly remembered by his host of friends and patients.

(Furnished by E. J. G. BEARDSLEY, M.D., F.A.C.P., Governor for Eastern Pennsylvania.)

DR. JAMES BIRNEY GUTHRIE

Dr. James Birney Guthrie (Fellow), the son of J. B. Guthrie and Clara Merrick, was born in New Orleans on January 3, 1876. His maternal grandfather was E. T. Merrick, Sr., Chief Justice of the Supreme Court of Louisiana, and his maternal grandmother was Caroline Merrick, pioneer worker in the ranks of the woman suffrage movement.

After his preliminary education in the public schools of New Orleans he entered Tulane University of Louisiana, from which he received the degrees of bachelor of science in 1896, and of doctor of medicine in 1900. He was the valedictorian of his class in the medical school. He served for two years as an intern at Charity Hospital. Immediately upon his graduation in medicine he was appointed Lecturer and Instructor in Materia Medica and Therapeutics at Tulane University. After four years he was promoted to the position of Associate Professor of Clinical Medicine, and in 1910 he was made Professor of Clinical Medicine, which position he held until 1928. In 1931 he was appointed Professor and Head of the Department of Medicine

in the new Louisiana State University Medical School. He was serving in this capacity at the time of his death.

Dr Guthrie was one of the first group established in New Orleans to conduct a clinical laboratory, in 1902. He was a pioneer in the field of clinical roentgenology, having set up one of the first x-ray apparatuses in New Orleans. At that time he had only an old static machine and improvised an interrupter of his own. From the time of his entrance into the Charity Hospital as an intern he served that institution uninterruptedly except for the term of his military service. He was a strict disciplinarian and his wards were always most carefully attended. He was the first roentgenologist at Touro Infirmary and when he retired from this field to devote himself entirely to clinical medicine he was named consultant in medicine at that institution. In this capacity he gave 10 years of devoted service to the diabetic clinic. At one time he was chairman of the staff at Hotel Dieu. Entering the army in 1918 as a major, he went overseas and was discharged in the spring of 1919 as lieutenant colonel. Subsequently he attained the rank of colonel in the Medical Reserve Corps.

Dr Guthrie was always active and interested in the work of organized medicine. He was a member of the Orleans Parish Medical Society, Louisiana State Medical Society, American Society of Tropical Medicine, American Medical Association, Association of Military Surgeons. He was elected to fellowship in the American College of Physicians on March 9, 1928. He was president of the Orleans Parish Medical Society in 1928.

Dr Guthrie had been ill for a number of weeks. The cause of his death, on March 8, 1932, was acute pericarditis.

(Furnished by RANDOLPH LYONS, M D, F A C P, Governor for Louisiana)

DR WILLIAM CHARLES HEUSSY

Dr William Charles Heussy (Fellow), Seattle, Washington, died March 21, 1932, following an operation for obstruction of the common bile duct, age 62.

Dr Heussy was born in Buffalo, N Y, attended the public schools there and later graduated from the University of Buffalo School of Medicine in 1895. He did postgraduate work at the Sloan Hospital and the London Hospital, of England, at the University of Edinburgh, at the Rotunda Hospital of Dublin, Ireland, and at the University of Pennsylvania. From 1906 to 1910, he was Lecturer on Hygiene at the Providence Hospital, from 1910 to 1912, President of the Board, Minor Hospital, 1913, Consulting Physician, City Hospital, 1916, Consulting Physician, King County Hospital, and from 1925 until 1928, Chief of the Medical Staff of the Columbus Hospital. He was Vice President of the Staff at this Hospital at the time of his death.

Dr Heussy was a member of the King County Medical Society, Washington State Medical Association, Fellow of the American Medical Association and past President of the Association for the Study of Internal Secretions. He was elected a Fellow of the American College of Physicians in 1917.
